DEDICATION

This second edition of the *Encyclopedia of Atmospheric Sciences* is dedicated to the memory of James Holton who was editor-in-chief of the first edition. He was a great researcher and colleague inspiring an entire generation of atmospheric scientists.

CONTENTS

<i>List of Contributors</i>	xxvii
<i>Preface to the First Edition</i>	xxxix
<i>Preface to the Second Edition</i>	xli
<i>Editor Biographies</i>	xlili
<i>Guide to Using the Encyclopedia</i>	xlvi

VOLUME 1

BASIC ATMOSPHERIC STRUCTURE AND CONCEPTS	1
Beaufort Wind Scale	1
<i>L Hasse</i>	
Wind Chill	7
<i>M Bluestein</i>	
Standard Atmosphere	12
<i>W W Vaughan</i>	
AEROSOLS	17
Aerosol–Cloud Interactions and Their Radiative Forcing	17
<i>U Lohmann</i>	
Aerosol Physics and Chemistry	23
<i>M Kalberer</i>	
Climatology of Stratospheric Aerosols	32
<i>L W Thomason and J-P Vernier</i>	
Climatology of Tropospheric Aerosols	40
<i>N Bellouin and J Haywood</i>	
Dust	48
<i>I N Sokolik</i>	
Observations and Measurements	53
<i>P H McMurry</i>	
Role in Radiative Transfer	66
<i>G A Ban-Weiss, and W D Collins</i>	

Role in Climate Change <i>N Bellouin</i>	76
Soot <i>P Chylek, S G Jennings, and R Pinnick</i>	86
Agricultural Meteorology and Climatology <i>E S Takle</i>	92
ARCTIC AND ANTARCTIC	98
Antarctic Climate <i>J Turner</i>	98
Arctic Climate <i>M C Serreze</i>	107
Arctic Haze <i>L M Russell and G E Shaw</i>	116
AIR SEA INTERACTIONS	
Freshwater Flux <i>J Schulz</i>	122
Momentum, Heat, and Vapor Fluxes <i>P K Taylor</i>	129
Sea Surface Temperature <i>W J Emery</i>	136
Surface Waves <i>A Benilov</i>	144
AVIATION METEOROLOGY	153
Aircraft Emissions <i>R R Friedl</i>	153
Aircraft Icing <i>M K Politovich</i>	160
Aviation Weather Hazards <i>A J Bedard, Jr</i>	166
Clear Air Turbulence <i>G P Ellrod (Retired), J A Knox, P F Lester, and L J Ehernberger (Retired)</i>	177
BIOGEOCHEMICAL CYCLES	187
Sulfur Cycle <i>P Brimblecombe</i>	187
Bromine <i>R von Glasow and C Hughes</i>	194
Heavy Metals <i>T D Jickells and A R Baker</i>	201

Iodine	205
<i>L J Carpenter</i>	
BOUNDARY LAYER (ATMOSPHERIC) AND AIR POLLUTION	220
Overview	220
<i>P J Mason and D J Thomson</i>	
Air Pollution Meteorology	227
<i>X-M Hu</i>	
Coherent Structures	237
<i>F T M Nieuwstadt and J C R Hunt</i>	
Complex Terrain	242
<i>J J Finnigan</i>	
Convective Boundary Layer	250
<i>M A LeMone</i>	
Microclimate	258
<i>M W Rotach and P Calanca</i>	
Modeling and Parameterization	265
<i>A A M Holtslag</i>	
Observational Techniques <i>In Situ</i>	274
<i>E F Bradley</i>	
Observational Techniques: Remote	284
<i>W M Angevine and C J Senff</i>	
Ocean Mixed Layer	290
<i>L Kantha and C A Clayson</i>	
Stably Stratified Boundary Layer	299
<i>L Mahrt</i>	
Surface Layer	305
<i>G L Geernaert</i>	
Urban Heat Islands	310
<i>J C Luvall, D A Quattrochi, D L Rickman, and M G Estes, Jr</i>	
Diurnal Cycle	319
<i>A Betts</i>	
CHEMISTRY OF THE ATMOSPHERE	324
Chemical Kinetics	324
<i>R P Wayne</i>	
Ion Chemistry	333
<i>J L Fox</i>	
Isotopes, Stable	348
<i>C A M Brenninkmeijer</i>	
Laboratory Kinetics	356
<i>D J Donaldson and S N Wren</i>	

Methane <i>E Dlugokencky, and S Houweling</i>	363
Observations for Chemistry (<i>In Situ</i>): Ozone Sonde <i>H G J Smit</i>	372
Observations for Chemistry (<i>In Situ</i>): Particles <i>T Deshler</i>	379
Observations for Chemistry (<i>In Situ</i>): Water Vapor Sonde <i>J B Smith</i>	387
Observations for Chemistry (Remote Sensing): IR/FIR (Satellite, Balloon and Ground) <i>H Fischer and F Hase</i>	401
Observations for Chemistry (Remote Sensing): Lidar <i>G Vaughan</i>	411
Observations for Chemistry (Remote Sensing): Microwave <i>J Waters</i>	418
Principles of Chemical Change <i>R P Wayne</i>	429
Radioactivity: Cosmogenic Radionuclides <i>D Lal</i>	437
Volcanoes: Composition of Emissions <i>M T Coffey and J W Hannigan</i>	446
Tracers <i>K A Boering</i>	450

VOLUME 2

CLIMATE AND CLIMATE CHANGE	1
Overview <i>D L Hartmann</i>	1
Carbon Dioxide <i>C L Sabine and R A Feely</i>	10
Climate Feedbacks <i>A E Dessler and M D Zelinka</i>	18
Climate Prediction: Empirical and Numerical <i>S Hastenrath</i>	26
Climate Variability: Decadal to Centennial Variability <i>D G Martinson</i>	33
Climate Variability: Nonlinear and Random Effects <i>M Ghil</i>	38
Climate Variability: North Atlantic and Arctic Oscillation <i>J W Hurrell</i>	47
Climate Variability: Seasonal and Interannual Variability <i>D S Gutzler</i>	61

Energy Balance Climate Models <i>G R North and K-Y Kim</i>	69
Global Impacts of the Madden–Julian Oscillation <i>C Zhang</i>	73
Greenhouse Effect <i>G R North</i>	80
History of Scientific Work on Climate Change <i>S Weart</i>	87
Intergovernmental Panel on Climate Change <i>K E Trenberth</i>	90
Nuclear Winter <i>A Robock</i>	95
Radiative–Convective Equilibrium Climate Models <i>N O Renno and X Huang</i>	102
Volcanoes: Role in Climate <i>A Robock</i>	105
CLOUDS AND FOG	112
Cloud Modeling <i>W-K Tao and M Moncrieff</i>	112
Contrails <i>P Minnis</i>	121
Cloud Microphysics <i>D Lamb</i>	133
Classification of Clouds <i>A L Rangno (Retiree)</i>	141
Climatology <i>S Warren, R Eastman, and C J Hahn</i>	161
Measurement Techniques <i>In situ</i> <i>D Baumgardner, J-F Gayet, A Korolev, C Twohy, and J Fugal</i>	170
Fog <i>P J Croft and B Ward</i>	180
Noctilucent Clouds <i>G E Thomas</i>	189
Stratus and Stratocumulus <i>R Wood</i>	196
CRYOSPHERE	201
Glaciers, Topography, and Climate <i>A B G Bush and M P Bishop</i>	201
Permafrost <i>T E Osterkamp and C R Burn</i>	208

Sea Ice	217
<i>M C Serreze, F Fetterer, and W F Weeks (Retired)</i>	
Snow (Surface)	227
<i>M Sturm</i>	
DATA ASSIMILATION AND PREDICTABILITY	237
Data Assimilation	237
<i>A C Lorenc</i>	
Ensemble-Based Data Assimilation	241
<i>Z Meng and F Zhang</i>	
Ensemble Prediction	248
<i>R Buizza</i>	
Predictability and Chaos	258
<i>L A Smith</i>	
DYNAMICAL METEOROLOGY	265
Overview	265
<i>J R Holton</i>	
Acoustic Waves	272
<i>K E Gilbert</i>	
Atmospheric Tides	287
<i>J Oberheide, M E Hagan, A D Richmond, and J M Forbes</i>	
Balanced Flow	298
<i>M E McIntyre</i>	
Baroclinic Instability	304
<i>R Grotjahn</i>	
Coriolis Force	313
<i>D W Moore</i>	
Critical Layers	317
<i>P Haynes</i>	
Hamiltonian Dynamics	324
<i>T G Shepherd</i>	
Hydraulic Flow	332
<i>R B Smith</i>	
Inertial Instability	334
<i>J A Knox</i>	
Kelvin–Helmholtz Instability	343
<i>P G Drazin</i>	
Kelvin Waves	347
<i>B Wang</i>	
Kinematics	353
<i>D D Houghton</i>	

Laboratory Geophysical Fluid Dynamics <i>R L Pfeffer</i>	360
Lagrangian Dynamics <i>I Roulstone</i>	369
Potential Vorticity <i>M E McIntyre</i>	375
Primitive Equations <i>A A White and N Wood</i>	384
Quasigeostrophic Theory <i>H C Davies and H Wernli</i>	393
Rossby Waves <i>P B Rhines</i>	404
Solitary Waves <i>J P Boyd</i>	417
Static Stability <i>J A Young</i>	423
Stationary Waves (Orographic and Thermally Forced) <i>S Nigam and E DeWeaver</i>	431
Symmetric Stability <i>H B Bluestein</i>	446
Vorticity <i>J R Holton</i>	451
Wave-CISK <i>C S Bretherton</i>	455
Wave Mean-Flow Interaction <i>M Juckes</i>	458
Waves <i>J R Holton</i>	464

VOLUME 3

ELECTRICITY IN THE ATMOSPHERE	1
Global Electrical Circuit <i>E R Williams</i>	1
Ions in the Atmosphere <i>K L Aplin and R G Harrison</i>	9
Lightning <i>M B Baker</i>	14
Sprites <i>W A Lyons</i>	20
Forensic Meteorology <i>L E Branscome</i>	28

GENERAL CIRCULATION OF THE ATMOSPHERE	33
Overview	33
<i>J M Wallace, D W J Thompson, and P Beresford</i>	
Angular Momentum of the Atmosphere	43
<i>D A Salstein</i>	
Energy Cycle	51
<i>R Grotjahn</i>	
Weather Regimes and Multiple Equilibria	65
<i>F Molteni</i>	
Mean Characteristics	73
<i>R Grotjahn</i>	
Teleconnections	90
<i>S Nigam and S Baxter</i>	
 GLOBAL CHANGE	 110
Climate Record: Surface Temperature Trends	110
<i>P D Jones</i>	
Sea Level Change	121
<i>R S Nerem</i>	
Upper Atmospheric Change	128
<i>R G Roble</i>	
Biospheric Impacts and Feedbacks	132
<i>B A Hungate and G W Koch</i>	
 GRAVITY WAVES	 141
Overview	141
<i>D C Fritts</i>	
Buoyancy and Buoyancy Waves: Optical Observations	153
<i>M J Taylor and W R Pendleton, Jr</i>	
Buoyancy and Buoyancy Waves: Theory	160
<i>T J Dunkerton</i>	
Gravity Waves Excited by Jets and Fronts	164
<i>R Plougonven and F Zhang</i>	
Convectively Generated Gravity Waves	171
<i>T P Lane</i>	
 HYDROLOGY, FLOODS AND DROUGHTS	 180
Overview	180
<i>R C Bales</i>	
Deserts and Desertification	185
<i>V P Tchakerian</i>	
Drought	193
<i>S Quiring</i>	

Flooding	201
<i>C A Doswell III</i>	
Groundwater and Surface Water	209
<i>S Ge and S M Gorelick</i>	
Modeling and Prediction	217
<i>Z Yu</i>	
Palmer Drought Severity Index	224
<i>L Nkemdirim</i>	
Soil Moisture	232
<i>A Robock</i>	
LAND-ATMOSPHERE INTERACTIONS	240
Overview	240
<i>R E Dickinson</i>	
Canopy Processes	244
<i>P D Blanken</i>	
Trace Gas Exchange	256
<i>J N Cape and D Fowler</i>	
LIDAR	262
Atmospheric Sounding Introduction	262
<i>P S Argall and R Sica</i>	
Backscatter	270
<i>C M R Platt and R L Collins</i>	
Differential Absorption Lidar	277
<i>S Ismail and E V Browell</i>	
Doppler	289
<i>R M Hardesty</i>	
Raman	296
<i>D N Whiteman</i>	
Resonance	305
<i>C S Gardner and R L Collins</i>	
Magnetosphere	309
<i>G K Parks</i>	
MESOSCALE METEOROLOGY	316
Overview	316
<i>D J Parker</i>	
Cloud and Precipitation Bands	323
<i>R M Rauber and M Ramamurthy</i>	
Gust Fronts	331
<i>R Rotunno</i>	

Hail and Hailstorms	334
<i>C Knight, N Knight, and H E Brooks</i>	
Mesoscale Convective Systems	339
<i>A Laing</i>	
Microbursts	335
<i>R M Wakimoto</i>	
Severe Storms	361
<i>C A Doswell III</i>	
Waterspouts	369
<i>J H Golden</i>	
Bow Echoes and Derecho	384
<i>M L Weisman</i>	
Density Currents	395
<i>P G Baines</i>	
Convective Storms: Overview	401
<i>M L Weisman</i>	
MESOSPHERE	411
Atomic Species in the Mesopause Region	411
<i>M G Mlynczak and L A Hunt</i>	
Ionosphere	422
<i>M C Kelley</i>	
Metal Layers	430
<i>J M C Plane</i>	
Polar Summer Mesopause	436
<i>R H Varney and M C Kelley</i>	
VOLUME 4	
MIDDLE ATMOSPHERE	1
Planetary Waves	1
<i>A K Smith and J Perlwitz</i>	
Polar Vortex	12
<i>M R Schoeberl and P A Newman</i>	
Quasi-Biennial Oscillation	18
<i>T J Dunkerton, J A Anstey, and L J Gray</i>	
Semiannual Oscillation	26
<i>K Hamilton</i>	
Stratospheric Sudden Warmings	30
<i>A O'Neill, A J Charlton-Perez, and L M Polvani</i>	
Transport Circulation	41
<i>S E Strahan</i>	

Zonal Mean Climatology <i>P Braesicke</i>	50
MOUNTAIN METEOROLOGY	57
Overview <i>R B Smith</i>	57
Cold Air Damming <i>B A Colle</i>	62
Downslope Winds <i>D R Durran</i>	69
Katabatic Winds <i>T R Parish</i>	75
Land and Sea Breezes <i>R A Pielke, Sr</i>	80
Lee Vortices <i>C C Epifanio</i>	84
Lee Waves and Mountain Waves <i>D R Durran</i>	95
Orographic Effects: Lee Cyclogenesis <i>C Schär</i>	103
Valley Winds <i>D Zardi</i>	114
NUMERICAL MODELS	135
Chemistry Models <i>M P Chipperfield and S R Arnold</i>	135
Coupled Ocean-Atmosphere Models: Physical Processes <i>M Zhang</i>	144
General Circulation Models <i>C R Mechoso and A Arakawa</i>	153
Methods <i>J Thuburn</i>	161
Model Physics Parameterization <i>D J Stensrud, M C Coniglio, K H Knopfmeier, and A J Clark</i>	167
Parameter Estimation <i>A Aksoy</i>	181
Parameterization of Physical Processes: Clouds <i>R Forbes, C Jakob, and M Miller</i>	187
Parameterization of Physical Processes: Gravity Wave Fluxes <i>M J Alexander</i>	194
Parameterization of Physical Processes: Turbulence and Mixing <i>A Beljaars</i>	200

Spectral Models <i>F Baer</i>	212
Mesoscale Atmospheric Modeling <i>R A Pielke, Sr</i>	219
Cloud-System Resolving Modeling and Aerosols <i>W-K Tao and T Matsui</i>	222
Large-Eddy Simulation <i>C-H Moeng and P P Sullivan</i>	232
Regional Prediction Models <i>B W Golding</i>	241
Convective Storm Modeling <i>M D Parker</i>	246
OBSERVATIONS PLATFORMS	255
Balloons <i>J-P Pommereau</i>	255
Buoys <i>J M Hemsley</i>	264
Kites <i>B B Balsley</i>	268
Radiosondes <i>W F Dabberdt and H Turtiainen</i>	273
Rockets <i>M F Larsen</i>	285
OCEANOGRAPHIC TOPICS	290
General Processes <i>N C Wells</i>	290
Surface/Wind Driven Circulation <i>R X Huang</i>	301
Thermohaline Circulation <i>R X Huang</i>	315
Water Types and Water Masses <i>W J Emery</i>	329
OPTICS, ATMOSPHERIC	338
Optical Remote Sensing Instruments <i>G G Shepherd</i>	338
Airglow Instrumentation <i>M Conde</i>	346

OZONE DEPLETION AND RELATED TOPICS	353
Long-Term Ozone Changes <i>N R P Harris</i>	353
Ozone as a UV Filter <i>J E Frederick</i>	359
Ozone Depletion Potentials <i>D J Wuebbles</i>	364
Photochemistry of Ozone <i>G K Moortgat and A R Ravishankara</i>	370
Stratospheric Ozone Recovery <i>D J Hofmann and R Müller</i>	380
Surface Ozone Effects on Vegetation <i>M Ashmore</i>	389
Surface Ozone (Human Health) <i>M Lippmann</i>	397
PALEOCLIMATOLOGY	404
Ice Cores <i>E J Steig</i>	404
Varves <i>R Gilbert</i>	411
RADAR	415
Cloud Radar <i>T Uttal</i>	415
Incoherent Scatter Radar <i>M P Sulzer</i>	422
Mesosphere—Stratosphere—Troposphere and Stratosphere—Troposphere Radars and Wind Profilers <i>G Vaughan and D Hooper</i>	429
Meteor Radar <i>N J Mitchell</i>	438
Polarimetric Doppler Weather Radar <i>R J Doviak and R D Palmer</i>	444
Precipitation Radar <i>S E Yuter</i>	455
Synthetic Aperture Radar (Land Surface Applications) <i>R K Vincent</i>	470
VOLUME 5	
RADIATION TRANSFER IN THE ATMOSPHERE	1
Radiation, Solar <i>Q Fu</i>	1

Absorption and Thermal Emission <i>R M Goody and X Huang</i>	5
Cloud-Radiative Processes <i>Q Fu</i>	13
Non-local Thermodynamic Equilibrium <i>M López-Puertas and B Funke</i>	16
Scattering <i>M Mishchenko, L Travis, and A Lacis</i>	27
Ultraviolet Radiation <i>K Stamnes</i>	37
Ultraviolet, Surface <i>R McKenzie and S Madronich</i>	45
SATELLITES AND SATELLITE REMOTE SENSING	51
Aerosol Measurements <i>R A Kahn</i>	51
Earth's Radiation Budget <i>N G Loeb and B A Wielicki</i>	67
GPS Meteorology <i>S S Leroy</i>	77
Measuring Ozone from Space — TOMS and SBUV <i>R D McPeters and R S Stolarski</i>	87
Orbits <i>S Q Kidder</i>	95
Precipitation <i>G Liu</i>	107
Remote Sensing: Cloud Properties <i>P Yang and B A Baum</i>	116
Research <i>M D King</i>	128
Surface Wind and Stress <i>W T Liu</i>	138
Temperature Soundings <i>A Dudhia</i>	145
Water Vapor <i>J E Harries</i>	157
SOLAR SYSTEM/SUN, ATMOSPHERES, EVOLUTION OF ATMOSPHERES	163
Evolution of Earth's Atmosphere <i>Y L Yung, M L Wong, and E J Gaidos</i>	163
Planetary Atmospheres: Mars <i>R M Haberle</i>	168

Planetary Atmospheres: Venus <i>P J Gierasch and Y L Yung</i>	178
Solar Terrestrial Interactions: Climate Impact <i>J D Haigh</i>	183
Solar Winds <i>S T Suess and B T Tsurutani</i>	189
Meteors <i>P Jenniskens</i>	195
STATISTICAL METHODS	201
Data Analysis: Empirical Orthogonal Functions and Singular Vectors <i>C S Bretherton</i>	201
Data Analysis: Time Series Analysis <i>G R North</i>	205
STRATOSPHERIC CHEMISTRY TOPICS	211
Overview <i>J A Pyle</i>	211
Halogens <i>D Toohey</i>	215
Halogen Sources, Anthropogenic <i>A McCulloch and P M Midgley</i>	221
Halogen Sources, Natural (Methyl Bromide and Related Gases) <i>S Yvon-Lewis and J H Butler</i>	228
HO _x <i>T F Hanisco</i>	233
Hydrogen Budget <i>J E Harries</i>	238
Reactive Nitrogen (NO _x and NO _y) <i>Y Kondo</i>	242
Stratospheric Water Vapor <i>K H Rosenlof</i>	250
STRATOSPHERE/TROPOSPHERE EXCHANGE AND STRUCTURE	257
Global Aspects <i>J R Holton</i>	257
Local Processes <i>J F Lamarque and P Hess</i>	262
Tropopause <i>M Dameris</i>	269

SYNOPTIC METEOROLOGY	273
Anticyclones <i>S J Colucci</i>	273
Forecasting <i>D Mansfield</i>	280
Weather Maps <i>R Reynolds</i>	289
Cyclogenesis <i>G J Hakim</i>	299
Extratropical Cyclones <i>A Joly</i>	304
Fronts <i>D M (David) Schultz and W Blumen</i>	337
Fronts in the Lower Stratosphere <i>A L Lang</i>	344
Frontogenesis <i>D M (David) Schultz</i>	353
Jet Streaks <i>P Cunningham and D Keyser</i>	359
Lake-Effect Storms <i>P J Sousounis</i>	370
Polar Lows <i>I A Renfrew</i>	379
Thermal Low <i>R H Johnson</i>	386
 THERMODYNAMICS	 391
Humidity Variables <i>J A Curry</i>	391
Moist (Unsaturated) Air <i>J A Curry</i>	394
Saturated Adiabatic Processes <i>J A Curry</i>	398
 Thermosphere <i>S C Solomon and R G Roble</i>	 402
 VOLUME 6	
TROPICAL CYCLONES AND HURRICANES	1
Overview and Theory <i>R A Tomas and P J Webster</i>	1

Hurricane Dynamics <i>Y Wang</i>	8
Hurricane Predictability <i>J A Sippel</i>	30
Hurricanes: Observation <i>F D Marks</i>	35
Tropical Cyclogenesis <i>Z Wang</i>	57
Tropical Cyclones and Climate Change <i>T R Knutson</i>	65
Tropical Cyclones in the Western North Pacific <i>J C L Chan</i>	77
Tropical Cyclones: Secondary Eyewall Formation <i>C-C Wu and Y-H Huang</i>	85
TROPICAL METEOROLOGY AND CLIMATE	91
El Niño and the Southern Oscillation: Observation <i>N Nicholls</i>	91
El Niño and the Southern Oscillation: Theory <i>P Chang and S E Zebiak</i>	97
Equatorial Waves <i>M C Wheeler and H Nguyen</i>	102
Hadley Circulation <i>J Lu and G A Vecchi</i>	113
Intertropical Convergence Zone <i>D E Waliser and X Jiang</i>	121
Intraseasonal Oscillation (Madden–Julian Oscillation) <i>R A Madden</i>	132
Madden–Julian Oscillation: Skeleton and Conceptual Models <i>A J Majda and S N Stechmann</i>	137
Monsoon: Overview <i>J Slingo</i>	146
Monsoon: Dynamical Theory <i>P J Webster and J Fasullo</i>	151
Monsoon: ENSO–Monsoon Interactions <i>K-M Lau</i>	165
Tropical Climates <i>S Hastenrath</i>	170
Walker Circulation <i>K-M Lau and S Yang</i>	177

TROPOSPHERIC CHEMISTRY AND COMPOSITION	182
Aerosols/Particles <i>J H Seinfeld</i>	182
Aliphatic Hydrocarbons <i>J Rudolph and O Stein</i>	188
Aromatic Hydrocarbons <i>I Barnes</i>	204
Biogenic Hydrocarbons <i>A Guenther</i>	214
Cloud Chemistry <i>P Herckes and J L Collett, Jr</i>	218
H ₂ <i>U Schmidt and T Wetter</i>	226
Hydroxyl Radical <i>K C Clemitshaw</i>	232
Mercury <i>J Munthe and J Sommar</i>	239
Oxidizing Capacity <i>D H Ehhalt, F Rohrer, and A Wahner</i>	243
Peroxyacetyl Nitrate <i>H B Singh</i>	251
Sulfur Chemistry, Organic <i>I Barnes</i>	255
Volatile Organic Compounds Overview: Anthropogenic <i>R G Derwent</i>	265
TURBULENCE AND MIXING	268
Overview <i>P Haynes</i>	268
Turbulence, Two Dimensional <i>P Bartello</i>	273
Turbulent Diffusion <i>A Venkatram and S Du</i>	277
WEATHER FORECASTING	287
Marine Meteorology <i>L Xie and B Liu</i>	287
Operational Meteorology <i>D R Novak</i>	293
Seasonal and Interannual Weather Prediction <i>J P Li and R Q Ding</i>	303
Severe Weather Forecasting <i>D J Stensrud, H E Brooks, and S J Weiss</i>	313

Wildfire Weather <i>J Coen</i>	323
Inadvertant Weather Modification <i>S A Changnon</i>	332
<i>Appendix 1: Physical Constants</i>	337

PREFACE TO THE FIRST EDITION

A half century ago the American Meteorological Society published the *Compendium of Meteorology*, which in a single volume of 1334 pages summarized the state of understanding of the atmosphere at that time. A perusal of the contents of that volume indicates that although a broad range of topics was covered, the vast bulk of the volume was devoted to traditional meteorological topics such as atmospheric dynamics, cloud physics, and weather forecasting. Barely 4 percent of the volume was devoted to articles related to atmospheric chemistry or air pollution and, of course, none of the volume was devoted to techniques such as satellites and remote sensing.

As Sir John Mason aptly notes in his foreword to the present work, the atmospheric sciences have expanded in scope enormously over the past 50 years. Topics such as atmospheric chemistry and global climate change, of only marginal interest 50 years ago, are now central disciplines within the atmospheric sciences. Increasingly, developing areas within the atmospheric sciences require students, teachers, and researchers to familiarize themselves with areas far outside their own specialties. This work is intended to satisfy the need for a convenient and accessible references source covering all aspects of atmospheric sciences. It is written at a level that allows undergraduate science and engineering students to understand the material, while providing active researchers with the latest information in the field.

More than 400 scientists, from academia, government, and industry have contributed to the 330 articles in this work. We are very grateful to these authors for their success in providing concise and authoritative summaries of complex subjects. As editors, we have benefited from the chance to learn from these articles, and we believe that all students and active scientists who want to increase their knowledge of the atmosphere will benefit enormously from access to this work.

We are also grateful to the 31 members of the Editorial Advisory Board who have guided us in our coverage of the very broad range of topics represented in this encyclopedia. Their willingness to suggest topics and authors, and to carefully review draft articles has contributed significantly to our success.

The production of this multivolume encyclopedia would not have been possible without the dedicated work of the staff of the Major Reference Works group at Academic Press. We are especially grateful to the Major Reference Work Development Manager, Colin McNeil, who has worked closely with us during the entire process. Finally, we appreciate the liberal use of color figures in the printed encyclopedia.

PREFACE TO THE SECOND EDITION

Since the publication of the first edition of the *Encyclopedia of Atmospheric Sciences*, significant advances in research have been achieved all across the broad and expanding spectrum of the field and related disciplines. In particular, climate science with primary input from the atmospheric research emerges as a new field and integrator of interlocking peripheral disciplines over the last decade. These events have demanded the solicitation of new and updated articles for the 2003 edition. Some articles from the earlier publication were judged to be of such a fundamental and enduring nature that they did not require modification. But huge amounts of new information from Earth-orbiting satellite observatories have brought much new insight to the field. In addition there are new findings in many areas such as the latest simulations of meteorological and climatic processes of interest as well as simulations and observations of the composition and interaction of the field's chemical constituents. While interest in the ozone hole and its ramifications may have reached a plateau, ever more understanding of the stratosphere and its role in climate change emerges. The study of past climates provides new means of testing climate models and theories. In weather prediction we see new progress on how data are to be better assimilated for much improved initialization of the forecast model leading to the promise of more accurate predictions of severe weather and tropical cyclones over longer lead times. These are just a few of the new features of the second edition.

The editors of the second edition are greatly indebted to our predecessors in the first edition. They set the outline of topics and solicited the original authors, while establishing a high standard for the content of this publication. In many cases we decided to reprint those articles or request only minor updates. Nevertheless, many articles in this edition are entirely original, based on which we also made significant reorganization of the content. We are proud of our product and hope it provides the same assistance to students, researchers, and practitioners throughout the science and engineering communities.

EDITOR BIOGRAPHIES

Gerald R North received his PhD in theoretical physics from the University of Wisconsin in 1966. After postdoctoral research at the University of Pennsylvania he became a faculty member in physics at the University of Missouri–St. Louis. He shifted his research focus to climate science research during his sabbatical year at the National Center for Atmospheric Research, where he won the Outstanding Paper Award in 1975. He moved to NASA Goddard Space Flight Center (GSFC) in 1978 where he was awarded the NASA Medal for Research Excellence. During his stay at GSFC, he was the proposer and first study scientist for the Tropical Rainfall Measuring Mission, which was launched in 1997 and is still orbiting in 2014.

He moved to Texas A&M University in 1986 as a university distinguished professor of atmospheric sciences where he served as department head from 1995 to 2003. He has served as editor-in-chief of the *Reviews of Geophysics* and is recognized as one of the most cited authors in geosciences (Web of Science). He has chaired and/or served on a number of national committees and is a Fellow of the American Geophysical Union, American Meteorological Society (AMS) and the American Association for the Advancement of Science, and winner of the Jule Charney Award for Research (AMS).

He has published about 150 refereed papers not including many book chapters and reviews. His books include *Paleoclimatology*, co-authored with Thomas Crowley, and *An Introduction to Atmospheric Thermodynamics* co-authored with Tatiana Erikhimova.

North's interests are focused on the use of mathematical and statistical tools to solve climate problems over a wide range of issues including: analytical solutions of simplified energy balance climate models, use of random field techniques in representing and interpreting climate data and model simulations, detection of deterministic signals in climate change, statistical analysis satellite remote sensing for mission planning and analysis of data, paleoclimate problems using simplified climate models.

John Pyle obtained a BSc in Physics at Durham University before moving to Oxford where he completed a DPhil in Atmospheric Physics, helping to develop a numerical model for stratospheric ozone studies. After a short period at the Rutherford Appleton Laboratory he moved to a lectureship at Cambridge University in 1985. In 2000 he was appointed professor of atmospheric science and since 2007 has been the 1920 professor of physical chemistry. He is a Professorial Fellow at St Catharine's College. He has been a codirector of Natural Environment Research Council's National Centre for Atmospheric Science, where he is currently Chief Scientist.

His research focuses on the numerical modelling of atmospheric chemistry. Problems involving the interaction between chemistry and climate have been addressed; these range from stratospheric ozone depletion to the changing tropospheric oxidizing capacity and have included the environmental impact of aviation, land use change, biofuel technologies, and the hydrogen economy. He has studied palaeochemistry problems as well as the projected atmospheric composition changes during the current century. He has published more than 250 peer reviewed papers.

He played a major role in building an EU stratospheric research programme in the 1990s, coordinating several major field campaigns. He has contributed to all the WMO/UNEP assessments on stratospheric ozone since the early 1980s and is now one of the four international cochairns on

the Scientific Assessment Panel, responsible for these assessments. He was a convening lead author in the IPCC Special report "Safeguarding the ozone layer and the global climate system," published in 2006.

He was elected Fellow of the Royal Society in 2004 and an American Geophysical Union Fellow in 2011. He was awarded the Cambridge ScD degree in 2012. Other honours and awards include membership of Academia Europaea (1993), Royal Society of Chemistry (Interdisciplinary award, 1991, and John Jeyes lectureship, 2008), and the Royal Meteorological Society Adrian Gill Prize, in 2004.

Fuqing Zhang is a professor with tenure in the Department of Meteorology at the Pennsylvania State University, with a joint appointment in the Department of Statistics, along with an endowed position as the E Willard & Ruby S Miller Faculty Fellow at the College of Earth and Mineral Sciences at the Pennsylvania State University. His research interests include atmospheric dynamics and predictability, data assimilation, ensemble forecasting, tropical cyclones, gravity waves, mountain plains and sea-breeze circulations, warm-season convection, and regional-scale climate. He earned his BS and MS in meteorology from Nanjing University, China in 1991 and 1994, respectively, and his PhD in atmospheric science in 2000 from North Carolina State University.

He spent seven years as an assistant and then associate professor at Texas A&M University before coming to Penn State University as a full professor in 2008. In 2000, he spent a year and a half as a postdoctoral fellow at the National Center for Atmospheric Research. He also held various visiting scholarship appointments at various academic and research institutions including the National

Center for Atmospheric Research in Boulder, Colorado; the Navy Research Laboratory in Monterey, California; NOAA/AOML Hurricane Research Division, Miami, Florida; Peking University and Nanjing University, China; the Chinese State Key Laboratory of Severe Weather in Beijing, China; and Laboratoire de Meteorologie Dynamique, École Normale Supérieure in Paris, France.

He has authored/co-authored about 130 peer reviewed journal publications and has given more than 160 keynote speeches or invited talks at various institutions and meetings. He has served as principal investigator/co-principal investigator for 30 federal or state-sponsored research grants. He has chaired/cochaired more than 10 scientific meetings or workshops. He also served on various review or advisory panels for numerous organizations that include National Science Foundation, Office of Naval Research, NASA, NOAA, and National Academies. He has also served as editor of several professional journals including *Monthly Weather Review*, *Science China*, *Atmospheric Science Letter*, *Acta Meteorologica Sinica*, and *Computing in Science & Engineering*.

He has also received numerous awards for his research and service. Notably, in 2007 he received the **Outstanding Publication Award** from the National Center for Atmospheric Research. In 2009, was the sole recipient of the American Meteorological Society's 2009 **Clarence Leroy Meisinger Award** "for outstanding contributions to mesoscale dynamics, predictability, and ensemble data assimilation." Most recently, he received the 2014 American Meteorological Society's **Banner Miller Award** "for valuable insights into incorporating real-time airborne Doppler radar measurements via ensemble data assimilation, leading to improvements in forecasts of tropical cyclone track and intensity."

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is not arranged by ordinary alphabetical order, but by alphabetical order according to 49 principal topic areas taken to allow all papers belonging to each principal topic to appear together in the same volume. Within each principal subject, article headings are also arranged alphabetically, except where logic dictates otherwise. For example, overview articles appear at the beginning of a section.

There are four features that help you find the topic in which you are interested:

- i. the contents list
- ii. cross-references to other relevant articles within each article
- iii. a full subject index
- iv. contributors

i. Contents List

The contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

ii. Cross-references

All of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an article as a See also list, serve four different functions:

- i. To draw the reader's attention to related material in other entries

- ii. To indicate material that broadens and extends the scope of the article
- iii. To indicate material that covers a topic in more depth
- iv. To direct readers to other articles by the same author(s)

Example

The following list of cross-references appears at the end of the article.

See also: **Biogeochemical Cycles:** Biogeochemistry of Iodine. **Stratospheric Chemistry Topics:** HO_x; Halogen Sources, Natural (Methyl Bromide and Related Gases); Halogens; Hydrogen Budget; Overview; Reactive Nitrogen (NO_x and NO_y).

iii. Index

The index includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole article, a part of an article, and a table or figure.

iv. Contributors

At the start of each volume there is list of the authors who contributed to that volume.

This article is reproduced from the previous edition, volume 1, pp 189–195, © 2003, Elsevier Ltd.

Introduction

For ships at sea, it has been widespread practice to include weather information into ship's logbooks to document the situation during its operations. For sail ships, wind information is most important. Beaufort adopted a scale to estimate the 'force of the wind' in 1805 when he was commanding officer of a man of war. The scale was formulated in terms of the effect of wind on sail ships of a certain type, but was subsequently used for other sail ships and steamers too.

Beaufort's scale of wind force was devised for use in the marine environment. However, since 1874, the Beaufort scale has been used in the international telegram code to transmit wind information from both sea and land. While Beaufort had used the behavior of sail ships in a given wind to define for what conditions common language terms like 'gentle breeze,' 'moderate gale,' 'whole gale,' or 'storm' should be applied, a different definition was required for land surfaces. Observers used certain indicators, e.g., behavior of flags, trees or drag plates, and feeling of wind in the face.

With today's knowledge of boundary layer meteorology, attempts to estimate the wind force over land appear questionable. One would need to use indicators of a known drag coefficient at a prescribed height in an open, level area without obstructions to the flow. Even then, correction for the roughness of the underlying terrain and for stability (e.g., day-night) would be required in order to make estimates comparable. Obviously, anemometer operation on land is a more direct method to determine wind speed instead of estimation. Use of the Beaufort scale to determine wind speed on land is not recommended and will not be discussed in the following.

Anemometer measurements on ships are difficult due to flow distortion. Also, only relative wind speed and direction are

measured. True wind needs to be calculated by vector addition of the independently measured course and speed of a ship, a source of additional error variance. Estimates of Beaufort force have therefore remained a tool for an extended period of time.

With improved types of rigging and transition from sail ships to steamers, the original definition of Beaufort forces was endangered. The appearance of the sea, wind effects on rigging, whistling of the wind, and other phenomena may have helped to pass on a tradition from experienced observers to younger colleagues, though not coded in words. Ship officers in the transition time likely had sufficient training on sail ships to estimate the wind force even on board steamers.

In 1927, a description of the Beaufort scale in terms of sea state was formulated by Petersen as a result of many years of experience (Table 1). His description was added later to the wind code by the International Meteorological Organization (IMO), the predecessor of the World Meteorological Organization (WMO). Obviously, IMO did not view reference to sea state as a redefinition, but rather as a written account of an existing practice. It is common habit to call the redefined scale the Beaufort scale of wind force too.

The use of Beaufort numbers for coding purposes had initiated early investigations into wind speed equivalents to Beaufort numbers, often called a 'Beaufort equivalent scale.' Measured wind speeds presumably could ensure consistent use of Beaufort numbers over land and would help to alleviate the difficulties resulting from change of ship types with time. Also, estimated wind force numbers do not really fit into the concepts of theoretical meteorology, where wind velocity is used in the basic Navier–Stokes equations.

Table 1 Definition of Beaufort force in terms of sea state

Beaufort number	Common name	Definition
0	Calm	Sea like a mirror
1	Light air	Ripples with the appearance of scales are formed, but without foam crests
2	Light breeze	Small wavelets, still short but more pronounced; crests have a glassy appearance and do not break
3	Gentle breeze	Large wavelets; crests begin to break; foam of glossy appearance; perhaps scattered white horses
4	Moderate breeze	Small waves, becoming longer; fairly frequent white horses
5	Fresh breeze	Moderate waves, taking a more pronounced long form; many white horses are formed (chance of some spray)
6	Strong breeze	Large waves begin to form; the white foam crests are more extensive everywhere (probably some spray)
7	Near gale	Sea heaps up and white foam from breaking waves begins to be blown in streaks along the direction of the wind
8	Gale	Moderately high waves of greater length; edges of crests begin to break into the spin drift; the foam is blown in well-marked streaks along the direction of the wind
9	Strong gale	High waves; dense streaks of foam along the direction of the wind; crests of waves begin to topple, tumble, and roll over; spray may affect visibility
10	Storm	Very high waves with long overhanging crests; the resulting foam, in great patches, is blown in dense white streaks along the direction of the wind; on the whole, the surface of the sea takes a white appearance; the tumbling of the sea becomes heavy and shock like; visibility affected
11	Violent storm	Exceptionally high waves (small- and medium-sized ships might be for a time lost to view behind the waves); the sea is completely covered with long white patches of foam lying along the direction of the wind; everywhere the edges of the wave crests are blown into froth; visibility affected
12	Hurricane	The air is filled with foam and spray; sea completely white with driving spray; visibility very seriously affected

Reproduced from World Meteorological Organization, 1970. The Beaufort Scale of Wind Force. Reports on Marine Science Affairs No. 3. World Meteorological Organization, Geneva.

From these introductory remarks, it can be seen that there are at least two tasks:

1. selection of a suitable relation between the force of wind and the wind velocity; and
2. correction for inhomogeneities in the time series of winds at sea.

Relation between Beaufort Force and Wind Velocity: A Problem of Physics and Regression Interpretation

A sail ship is not a well-defined tool to measure wind speed. The same is true for the appearance of the sea surface that depends to some degree on the history of both the wind field and the wave field and even on turbulence in the atmospheric boundary layer over the sea. In retrospect, it appears wise that only a coarse scale was devised for a measure of wind force. As only a statistical relation can be expected, requirements on such a scale need to be defined.

Following Lindau, an optimal Beaufort equivalent scale is required to convert Beaufort estimates into wind speeds such that derived climatological quantities like means and variances agree with respective quantities from unbiased wind measurements.

The attempts to derive a Beaufort equivalent scale differ in the meteorological setup of the experiment and in the subsequent statistical interpretation. Difficulties exist in both parts. It appears that misunderstandings in the interpretation of statistical methods have hampered the development of and agreement on a Beaufort equivalent scale more than questions of measurements and exposure.

One-Sided Regressions

Derivations of Beaufort equivalent scales typically use regression techniques. For a pair of variables (x , y), two

regression curves can be derived, depending on which of the variables are considered 'independent.' A common notion of regression sounds like: "The regression of y on x gives the best estimate (by the method of least squares) of y for a given independent x , and, similarly, the regression x on y gives the best estimate of x as a function of independent y ." The one-sided regression implies the 'independent' variable as nonrandom and attributes all random variation to the other, as can be seen if one follows the derivation, e.g., for a linear fit. The same is true in nonlinear regression, where typically means of the dependent variable are calculated for intervals of the independent variable.

The physical problem of one-sided regressions is seen in the following. If an equivalent scale from data including error variances in both variables is determined, the spread of the independent variable is increased by its random errors and the resulting regression line has too small a slope. Applying this regression to climatological variables (e.g., monthly mean wind speed and variance), the derived variances will deviate systematically from respective quantities determined from unbiased measured winds.

In the development of Beaufort equivalent scales, two approaches have been used:

1. We take the Beaufort number as well determined and calculate the mean velocities for each interval of Beaufort number; i.e., a nonlinear regression of wind velocity is used on Beaufort number.
2. We argue that the average wind velocity is well measured and the random variations stem from imperfect estimation of Beaufort numbers. In this case, the regression of Beaufort force on wind velocity is the given choice.

The pitfall is seen in the following: in one-sided regression, the independent variables are treated as nonrandom and all variability from both axes is ascribed to the dependent variable.

The first approach was applied in early investigations listing wind speeds averaged for each Beaufort number, although difficulties of both Beaufort observations and the exposure and calibration of wind instruments were discussed.

However, there are good arguments to use the second approach, the regression of estimates to measured speeds. It is known that Beaufort numbers are estimates only, which are influenced by different external conditions and by uncertainties in the observer's judgment. Also, the quantization error is larger for estimates due to the larger intervals of the Beaufort scale compared to speeds in meters per second. It is not unreasonable to infer the error of Beaufort number estimation to be much larger than the uncertainty of anemometer measurements. Köppen in 1888 already advocated the averaging of Beaufort estimates for intervals of measured speeds in order to establish an equivalent scale.

IMO adopted a scale for official use, corresponding to today's WMO code 1100, that was established in 1906 by Simpson, Meteorological Office, London, using regression of Beaufort estimates to measured speeds as recommended by Köppen.

Two-Sided Regressions

It is evident that both Beaufort force estimates and velocity measurements contain random errors, and a two-way regression would be the appropriate tool. The best relation between two random variables lies between the two one-sided regressions. For linear regressions, in the absence of information on the respective error variances, the best choice would be the bisector of the angle between the two one-sided regression lines. It minimizes the orthogonal distances of observed points from the line. This is equivalent to assuming the error variances to be the same fraction of total variance for each of the variables. This so-called orthogonal regression is certainly better than a one-sided regression, when both variables are subject to random errors. However, in a given case, the fraction of error in the total variance of each variable need not be the same and an improved technique is required.

For illustration, consider the observations at the Ocean Weather Station (OWS) K in Figure 1. The two one-sided regression lines and the orthogonal regression line are plotted together with the monthly means of anemometer measurements at OWS K and Beaufort estimates from ships in the vicinity. The fit through the monthly means deviates from the orthogonal regression in the direction toward the one-sided regression of Beaufort numbers on measured speeds. This implies that the uncertainty of Beaufort estimates is a larger fraction of the total variance than that of anemometer measurement.

The orthogonal regression yields a better Beaufort equivalent scale than any of the one-sided regressions – in the sense to better reproduce the means of wind speed from Beaufort estimates. The agreement is even better than one would expect from error estimates of wind speed measurements and Beaufort estimates. The reason for this is seen in the natural variability between measurements colocated in space and time that enters as 'unexplained' variance in the regression too.

Figure 1 Relation between Beaufort force and wind speed (kn), based on observations from OWS K and ships within 500 km from OWS K, period 1960–71. One-sided and 'orthogonal' linear regressions (thin lines) are compared with monthly means. The linear fit of monthly means (full line) deviates from the best linear regression calling for explicit consideration of error variances. Reproduced from Lindau, R., 1994. Eine neue Beaufort-Äquivalentskala. Berichte Institut für Meereskunde Kiel, Kiel No. 249.

An Optimized Beaufort Equivalent Scale

Wind speed measurements at OWSs and Beaufort estimates from passing voluntary observing ships (VOSs) were used in several attempts to derive an improved equivalent scale. Some averaging is needed to reduce errors of measurements in respective observations and also to account for the natural variability that enters because VOSs pass OWSs at some distance.

Lindau developed a sophisticated method to determine effective variances. From simultaneous observations of pairs of VOSs, differences were obtained and variances calculated as a function of distance between the ships. Extrapolating to fictitious zero distance, the error variances of VOSs were obtained. Using the same technique on pairs of OWSs and VOSs, the error variances of OWSs were also determined.

Knowing the variances, influence of errors and natural variability could be reduced by averaging in time for OWSs and space for VOSs. A suitable area around an OWS was selected to contain the same variance in space from VOS than at the OWS in time for 1 day. This radius and the appropriate number of VOS observations were determined separately for each OWS and each season.

With the error variance at OWS and VOS reduced by averaging the appropriate number of observations, and the natural variability being assured to be the same, the 'orthogonal' regression yields the correct relation. Instead of straight lines, Lindau used the method of cumulative frequencies in order to admit nonlinearities. Anemometer heights at weather ships are near 25 m. Wind measurements at OWSs were reduced to 10 m

Table 2 Selection of Beaufort equivalent scales, given in m s^{-1}

Beaufort	0	1	2	3	4	5	6	7	8	9	10	11	12
IMO (1926) 6 m ^a	0.0	1.1	2.5	4.3	6.3	8.6	11.1	13.8	16.7	19.9	23.3	27.1	
Code 1100 10 m ^a	–	0.8	2.4	4.3	6.7	9.4	12.3	15.5	18.9	22.6	26.4	30.5	~34.8
Lindau 10 m ^b	0.0	1.2	2.7	4.6	7.2	9.7	12.1	14.6	17.3	20.2	23.4	27.1	31.4
CMM-IV 18 m ^a	0.8	2.0	3.6	5.6	7.8	10.2	12.6	15.1	17.8	20.8	24.2	28.0	~32.2
Lindau 25 m ^c	0.1	1.2	2.8	4.9	7.7	10.5	13.1	15.9	18.9	22.2	26.0	30.3	35.4
Kaufeld 25 m ^d	0.4	1.9	4.1	6.4	8.7	11.0	13.4	15.9	18.7	21.8	25.1	28.6	32.4
Reduction factor 25–10 m			0.96	0.94	0.94	0.92	0.92	0.92	0.92	0.91	0.90		

Often knots ($1 \text{ kn} = 0.5144$; $1 \text{ m s}^{-1} = 1.944 \text{ kn}$) are used as the unit. The last line gives the reduction factor to compare equivalent scales for reference heights of 25 and 10 m, derived for the ensemble of measurements at North Atlantic OWSs.

height using a diabatic wind profile. The resulting equivalent scale is thus applicable to 10 m height. The results are given in Table 2 and depicted in Figure 2.

Discussion of Heights for Equivalent Wind Velocities

Beaufort estimates per se have no natural height above the sea surface. However, equivalent scales give wind speeds. Because of the approximately logarithmic wind profile in the atmospheric boundary layer, for applications of the Beaufort equivalents the corresponding height needs to be known.

Code 1100 in use from 1926 to 1946 was believed to refer to 6 m height. Since the required standard height of anemometers had changed from 6 to 10 m, a slightly changed

code 1100 was introduced in 1946 by WMO, supposedly applicable to 10 m height. Both versions of code 1100 were based on data sets into which observations from the Scilly Islands entered in a relatively large number. However, wind speeds were taken at the small island of St Mary's that features several heights reaching 30–50 m above mean sea level. It is uncertain to what height in undisturbed flow over water the measurements would correspond.

Lindau's improved equivalent scale settled the problem of reference height by using anemometer measurements of known heights and reducing winds to heights of 10 m individually with the aid of the diabatic wind profile. He could also show that for the WMO code 1100 of 1946 a reference height of 10 m is reasonable. The anemometer measurements at OWSs are not corrected for flow distortion. One can hope that the exposure of instruments at OWSs and the mode of ship operation at the station will make this an acceptable error.

Often a reduction of velocity measurements from anemometer height to reference height is necessary. Typically, a constant reduction factor, derived from the neutral wind profile, is used. However, slightly unstable conditions prevail at most parts of the oceans, approaching near-neutral conditions at higher wind speeds. For the mix of stabilities at the North Atlantic OWS, a reduction factor of 25–10 m decreases with wind speeds from ~0.94 to ~0.90; see Table 2.

Discussion of Other Scales

The matter of Beaufort equivalent scales found renewed interest in the second half of the twentieth century. Especially within the wave modeling community, still in 1990 the opinion prevailed that the WMO Beaufort equivalent scale (code 1100) is in error. For example, the WMO Commission of Marine Meteorology produced a scale – known as CMM-IV scale – using regression of anemometer measurements on Beaufort estimates, similar to the scale of Cardone. Regrettably, in the new derivations the variable with small error variances was regressed on a variable with obviously much larger error variances, leading to biased scales.

Fortunately, the governing bodies of WMO adhered to code 1100, though admitted application of CMM-IV and similar scales for scientific purposes, so-called scientific

Figure 2 Different Beaufort equivalent scales: code 1100 (10 m reference height), crosses; CMM-IV (25 m height), circles; Kaufeld (25 m height), dashes; and Lindau (25 m height), dots. Code 1100 determined by regression of Beaufort on wind speed, CMM-IV by wind speed on Beaufort, Kaufeld, and Lindau from cumulative frequencies.

equivalent scales. In retrospect, the scientific scales are the wrong choice. They give biased climatological means. The use of 'scientific' scales in wave modeling is even more questionable since this practice is at variance to the use of code 1100 in operational weather analysis and forecasts. Seen in the light of the correct derivation by Lindau, it turns out that the insight of Köppen and Simpson around 1900 resulted in a scale, WMO code 1100, that is less biased than some scientific scales of 70 years later. (It might be noted that the description of Köppen's method in the WMO Report on marine science affairs of 1970 is reversed to what Köppen advocated and used, i.e., regression of Beaufort on wind speed.)

The regression technique of cumulated frequencies applied by Lindau had been used by Kaufeld before him. It has the advantage to account for nonuniform distribution of observations at the tails of the frequency distribution. This technique can be seen as the nonlinear equivalent to the 'orthogonal' two-sided regression. Though the different error variances of the two variables were not accounted for, Kaufeld's scale is certainly preferable to the so-called scientific scales derived by one-sided regression of wind speed on Beaufort force.

Kent and Taylor reviewed a selection of Beaufort equivalent scales and the techniques used in their derivation, and concluded that the Beaufort equivalent scale of Lindau is to be preferred when creating a homogeneous monthly mean wind data set from anemometer and visual winds in Comprehensive Ocean Atmosphere Data Set (COADS).

Time Dependence of Beaufort Estimates

Increasing interest in long time series of climate data inevitably leads to the question of whether the reported winds from the oceans are homogeneous in time. The slow change of observing practices was mentioned. There have been changes in coding practices too. Originally, Beaufort forces were used in transmitting data. Effective in 1948, WMO changed from Beaufort forces to transmit wind speeds in knots (1 knot equals 1 nautical mile per hour or 0.51 m s^{-1}). For a short time of transition, the erroneous use of codes may have influenced reported winds, but no long-term trend is expected.

There are an increasing number of ships carrying anemometers. Determination of true wind from anemometer measurements requires vector subtraction of course and speed of the ship, certainly an additional source for errors and inaccuracies. Also, the code indicating the data as either measured (anemometer) or estimated (Beaufort scale) is known to be less reliable. Peterson found frequency distributions of *estimated* winds to show significant secular changes and ships carrying anemometers to report higher estimated winds than ships without anemometers. The latter is most embarrassing, since no single reason and simple cure can be given.

On the other hand, a trend toward higher wind speeds could well be an indication of climate change. Growing amounts of greenhouse gases change the radiation balance. At the oceans, surplus energy can fuel atmospheric circulations, e.g., midlatitude and tropical storms. In fact, plotting the recorded wind speeds at face value shows significant trends.

Ramage showed that reported ocean wind speeds exhibit secular changes. He studied monthly mean wind speeds at the

Singapore–South China route, taking along the track pressure differences for reference. He attributed the decrease of wind speed prior to World War II to transition from sail to steam and the increase thereafter to a growing portion of ships carrying anemometers; a true secular trend could not be isolated.

Taking the evidence together suggests deriving time-dependent corrections for the Beaufort equivalent scale. The obvious tool is to use independently measured pressure gradients as reference, presuming the relation between surface wind and pressure field to be invariant. Unfortunately, ships tend to follow certain lines providing pressure differences rather than full horizontal pressure gradients. Lindau developed a statistical method to derive wind velocities relative to pressure gradients. He used simultaneous wind vectors and pressure differences from pairs of ships within reasonable distance. Pressure differences were sorted according to the relative wind direction and the magnitude of pressure gradient obtained by fit (Figure 3). Errors in wind direction estimated at VOSs are equivalent to a smoothing of the pressure differences and have been accounted for.

Taking 1960–71 as the base period, time-dependent corrections for estimated wind speeds have been derived for the North Atlantic between 20° N and 60° N . From the uncorrected data, one would identify long-term trends of different sign before and after World War II, while corrected for drift of scale the apparent increase of wind speed after 1950 disappears (Figure 4). Considering the full time range from 1890 to 1990,

Figure 3 Determination of geostrophic wind V_g as reference for time-dependent calibration of Beaufort estimates, based on pressure differences from pairs of ships. Pressure differences are shown as a function of wind direction relative to the direction of paired observations. The dashed line is obtained considering the error variance of wind direction. Based on data from the North Atlantic between 40° N and 50° N , January, period 1960–71. Reproduced from Lindau, R., 1995. Figure 4 Mean wind speed anomalies for the North Atlantic Ocean between 20° N and 60° N, converted from Beaufort estimates using the Lindau scale for 10 m height. Upper panel uncorrected; lower panel corrected with reference to pressure gradients. Reproduced from Lindau, R., 2001. *Climate Atlas of the Atlantic Ocean*. Springer Verlag, Berlin, Heidelberg.

there appears to be no physically significant trend over the North Atlantic Ocean.

Unresolved Issues

The low and high velocity ends of the Beaufort scale are less well determined. This is not important for the low wind speeds. For the high wind speeds, obviously too few observations are available to establish Beaufort equivalents. In typical listings, speed ranges for the Beaufort numbers are given as well as averages. Beaufort number 12 is usually taken as unlimited, i.e., with no equivalent speed assigned. Bortkovskii fitted a Maxwell distribution to high wind speeds from winter Atlantic OWS observations for the description of storminess in air–sea interaction studies. This method could be used to establish a mean equivalent velocity for Beaufort 12, under the premise of stationarity of the time series.

Beaufort equivalent scales have been determined mainly from observations at the North Atlantic but accepted by WMO for international use. If sorted by ship call sign (corresponding roughly to national origin of data), there are differences in mean results. Noting differences in time as well as in national use, it would be desirable to check the equivalence scale for consistency at other oceans too. The indication that anemometer-carrying ships report estimated winds higher than ships without an anemometer calls for further study too.

Collecting marine surface observations has been a habit of generations. In the beginning, national services collected logbooks. Later, data were transferred to punched cards and collected sets (referred to as ‘decks’) binationally exchanged. Multinational collections finally resulted in the COADS. Wind observations at sea were collected more systematically since about 1860 – welcome information for climate studies. It is hoped that the methods available now will be adopted by the

international community to provide for the production of a homogeneous, unbiased time series of ocean wind fields to be used in future research.

Wind Chill

Synopsis

Wind Chill is the name given to the effect of increased heat loss from the skin exposed to cold, windy weather. It is characterized by the wind chill temperature (WCT) defined as that air temperature with no appreciable wind effecting the same heat loss rate as the actual temperature and wind. This article provides a history of how the WCT was originally developed, what flaws were found in that research, and how the current chart of WCT versus temperature and wind speed was arrived at. The chart is provided in both Fahrenheit and Celsius units.

Introduction

All bodies exposed to colder air will lose heat because of the temperature difference between their skin and the air. The rate of heat loss in still air is a function of that difference as well as the amount of exposed area of the body, the conditions at the body's surface, and whether there is radiant energy available. These are well-known principles of the branch of science and engineering called 'thermodynamics.'

It is also known that if the air is moving across the body's surface, the rate of heat loss increases. With increases in air speed, or wind, the heat loss rate increases, a process known to engineers as forced convection. This increase in heat loss rate affects humans exposed to cold, windy weather and has become known as wind chill. The human body feels colder, particularly at the unclothed areas of skin, when there is wind than when there is no appreciable wind at the same temperature. Accelerated heat loss rates can lead to frostbite if the skin remains exposed long enough. The greater the wind speed, the greater the heat loss rate, and the faster will frostbite set in as the skin temperature drops.

Meteorologists have long sought to characterize these effects of the wind on humans. The forced convection process described above has been called the 'wind chill factor.' What has been desired is a quantitative measure of this effect that can be used in weather forecasting and reporting. A number of such measures have been utilized. The heat loss rate per unit area of exposed skin was utilized in Canada until recently. A proposal to report the skin temperature has been presented by researchers in Israel. By far the most accepted measure is the wind chill temperature (WCT) used in the United States and other countries. The WCT is defined as that air temperature with no appreciable wind that would effect the same heat loss rate from exposed skin as that due to the actual dry bulb temperature with wind. The term 'no appreciable wind,' often referred to as 'still air,' is used because the body is considered to be in motion at all times relative to the air. After all, everyone is at least breathing, and most likely moving to get out of the wind on a cold day.

A WCT chart is currently utilized by the US National Weather Service (NWS) and the Canadian weather service, Environment Canada (EC). For a given air temperature and wind speed as reported from a weather station, the WCT may be read from a chart such as that shown in [Figure 1](#), which includes versions in both English and metric units. This new

chart, established in November 2001, includes warnings of a risk of frostbite based on time of exposure.

Numerous researchers had been critical of the original chart, which was developed from research done by Siple and Passel in Antarctica during the 1940s and was in use by the NWS from 1973 to 2001. The origin of the first chart will be reviewed and criticism of its accuracy will be discussed. The basis for the new chart will be described. Since wind chill results in individual discomfort, a degree of subjectivity will always be present in such a concept. Many physical factors may also play a part in an individual's response to wind chill, such as the amount of sunshine present, the wind direction and variability, moisture in the air, and the presence of ground structures that modify the wind.

Origin of the Wind Chill Temperature Calculation

The need to properly clothe American servicemen for the rigors of the European winters of World War II gave rise to the first formal study of wind chill. Two US Army researchers, Paul Siple and Charles Passel (hereafter referred to as S & P), investigated the effect of wind on the heat loss from a body during the Antarctic winter of 1941. The 'body' was a plastic cylinder containing 250 g of water. The cylinder was made of cellulose acetate with dimensions 14.9 cm long, 5.7 cm in diameter, and 0.3 cm thick. A therm ohm, a device that measures temperature via electrical resistance, was immersed in the water and the cylinder was sealed. The cylinder was suspended above the recording station with a thermohm next to it to record dry bulb temperatures. Nearby, a cup anemometer recorded the wind speed. As the cylinder lost heat, the water would begin to freeze. Knowing the heat of fusion of water, the time the water spent at the freezing point would yield the heat loss rate. That time was determined by monitoring the water temperature. The heat loss rate was then modified by the container area exposed and the difference between the container temperature (assumed to be 0 °C) and the air temperature to arrive at a heat transfer coefficient. Such coefficients are necessary if one is to relate the experimental results to other bodies with other temperatures. The units of heat loss rate employed by S & P were kilogram-calories (kcal) per hour, with heat transfer coefficients in units of kcal per hour per square meter per degree Celsius. Average air temperatures ranged from −56 °C to −9 °C, and wind speeds from still air to 12 ms^{−1} (27 miles h^{−1}). Heat transfer

Frostbite may occur in 30 min or less

Figure 1 (a) The new wind chill temperature (WCT) Index chart, with T = air temperature in °F and V = wind speed in miles h⁻¹ at 33 ft elevation. WCT (°F) = $35.74 + 0.6215 T - 35.75 V^{0.16} + 0.4275 TV^{0.16}$. (b) The new WCT Index chart, with T = air temperature in °C and V = wind speed in km h⁻¹ at 10 m elevation. WCT (°C) = $13.12 + 0.6215 T - 11.37 V^{0.16} + 0.3965 TV^{0.16}$.

coefficients were plotted against wind speed and the original data are shown in Figure 2. The authors mistakenly called the coefficient as the cooling rate in this figure. The relationship between the heat transfer coefficient and the wind speed was determined by a best-fit line through the recorded data points. This line, shown solid in the figure, is represented by eqn [1], where h = heat transfer coefficient, in kcal h⁻¹m⁻² °C⁻¹ and v = wind speed, in m s⁻¹.

$$h = 10\sqrt{v} + 10.45 - v \quad [1]$$

The heat loss rate for a body would then be given by eqn [2], where Q = heat loss rate, in kcal h⁻¹, A = surface area exposed, in m², T_s = surface temperature, in °C, and T_a = air temperature, in °C.

$$Q = hA(T_s - T_a) \quad [2]$$

Under the Antarctic conditions, the heat loss from the container surface would have been due to forced convection created by the air moving over the surface plus radiation from the surface to the surrounding air because of the

temperature difference. Equation [1] indicates that heat loss would increase with wind speed up to a value of 25 m s⁻¹, or about 56 miles h⁻¹, and decrease thereafter.

Armed with a relationship between wind speed and the heat transfer coefficient, the authors then set about to apply this to humans. Using the concept of a WCT as defined above, the actual heat loss rate due to air temperature and wind speed is set equal to the rate when the air would be at the WCT and still. This is expressed mathematically as eqn [3], where h_0 = heat transfer coefficient when the air is still (kcal h⁻¹ m⁻² °C⁻¹).

$$hA(T_s - T_a) = h_0A(T_s - \text{WCT}) \quad [3]$$

The authors assumed a constant skin temperature of 33 °C for T_s . It was further assumed that the heat transfer coefficient in still air would be that value found by eqn [2] for an air speed of 1.79 ms⁻¹, (~4 miles h⁻¹). This had become the accepted value for still air. Equation [3] may be solved for WCT for given values of dry bulb temperature and air speed, since the areas on either side of the equation are the same.

Figure 2 Wind velocity versus total heat transfer coefficient from Siple and Passel. (Reproduced with permission from Siple and Passel (1945).)

In Canada, only the left side of eqn [3], equal to the heat loss rate, was utilized. Since the body surface area can vary, the heat loss rate was expressed per unit area. The value of h is determined from eqn [2]. The air temperature is subtracted from a skin temperature of 33 °C. The result was called the wind chill index (WCI) and the units were converted to watts per square meter. Understandably, most citizens of Canada had difficulty with such an index.

In the dissemination of the original wind chill chart, the NWS had stated that no specific rules exist for determining when wind chill becomes dangerous. As a general rule, they stated that the threshold for potentially dangerous wind chill conditions was about -29 °C (-20 °F). Mitigating circumstances such as strong sunshine would require colder threshold temperatures.

Problems with the Wind Chill Calculation

A number of researchers expressed concern about the procedure used to calculate the WCT. Most of these related to the method used by S & P. The water in their container would not have frozen at the same rate throughout; using only one thermohm could create variability in the data. The data shown in Figure 2 are quite variable. In addition, the assumption of a container surface temperature of 0 °C ignored the thermal resistance of the container. Heat transfer theory shows that the surface temperature would have been below freezing. Perhaps the greatest problem with S & P's approach is the choice of 33 °C for human skin temperature. Human skin exposed to very cold temperature drops well below this value rapidly. If eqn [3] is solved for WCT, one obtains eqn [4].

$$WCT = \frac{h}{h_0}(T_a - T_s) + T_s \quad [4]$$

Since h is always greater than h_0 , as T_s is lowered, WCT is increased. This gave rise to a consensus among researchers that the first WCT chart exaggerated the effect of the wind by providing WCTs that were lower (colder) than they should be.

Another problem with that WCT chart had a more modern root. Wind speeds are recorded at official weather stations 10 m above the ground. Wind speeds at ground level are significantly less, owing to surface effects and structures such as buildings and trees. This means that humans are exposed to less wind than is reported and thus further results in higher WCTs.

Other problems cited include extrapolation of the results for a small container to the larger human body, and the difference between the thermal resistance of the plastic container and that of human skin.

Even with all these problems, it is fair to say that the WCT and the WCI have served a worthwhile purpose for many years. They have made the public aware of the effect of wind on winter comfort and have encouraged the citizenry to respect the dangers of low temperatures combined with high wind speeds.

While the wind chill concept has made the public aware of the dangers of high wind speed combined with cold temperatures, many persons misunderstand what the WCT actually represents. Many believe that if an object such as their automobile is left outside for a long period it will reach the WCT. The public should be led to understand that a low WCT means the object will get to the actual air temperature faster: If the air temperature is above freezing, the skin will not freeze even though the WCT is well below freezing. As a possible remedy,

the current NWS protocol calls for reporting the WCT only when the actual air temperature is at freezing or below.

Proposals to Improve the Wind Chill Determination

A major advance in the attempts to improve the accuracy of the WCT or WCI was made by Oszcewski in Canada in 1995. He created an instrumented model of the human head, surmising that the head is the most often exposed part of the body in winter. The model included a power source to maintain internal temperature similar to that of a human head and temperature sensors at the model's surface. The part of the model considered as representing the human face was turned into a wind generated in a wind tunnel. The resultant heat transfer effect was similar to that of an upright cylinder in a crosswind. Such a cylinder has been extensively studied in the heat transfer literature. Bluestein and Zecher used a similar approach but with a theoretical analysis only. They used a full cylinder to represent the adult head and produced WCTs that were higher than the original National Weather Service chart.

Oszcewski felt that the face rather than the entire head should be the area of interest in determining wind chill effects. Thus, only the front side of the equivalent cylinder would be considered in evaluating the WCI and WCT. Heat transfer experiments have shown that at low wind speeds, effectively the calm condition, the heat loss from the front of such a cylinder (the surface facing the wind) is greater than that from the rear surface. Thus, when the face rather than the entire head is considered (a half-cylinder rather than a whole cylinder), the value of h_0 in eqn [3] tends to be higher. This makes the WCT higher (less cold). When coupled with a more realistic skin surface temperature, the resultant WCT values were higher than those in the chart derived from the work of S & P and higher than those of Bluestein and Zecher.

As noted above, wind speeds are recorded at 10 m above the ground; modern researchers have sought to take this factor into account in modifying the WCT. A formula developed by Steadman has shown that wind speed at the level of the typical adult face in an open area is about two-thirds of that reported at the weather station; forests and urban settings have an even greater reduction. Thus, calculated WCTs should use a corrected wind speed, resulting in still higher values for the WCT.

Another consideration in the improvement of the determination of the WCT is the addition of the sunshine factor. Clearly, bright sun adds a warming effect to exposed skin and should perhaps be included in the WCT determination. Even partial sun, or partly sunny (or cloudy) conditions, can affect the heat loss from the skin. This effect would depend on the time of year and the latitude, and so would add some complexity to the calculation of the WCT. Current meteorological capability exists to evaluate this factor and may help the public to better evaluate environmental conditions.

Many researchers believe that wind chill should be evaluated for a whole-body human model, including clothing and, in some cases, an assumed metabolic activity rate. One of the most complete analyses has been done by Steadman but his formula is complicated. His work results in an Apparent Temperature (AT), which has the advantage of being applicable

for both cold and hot weather conditions. This is certainly a valuable research tool but may be too complex for use in weather forecasts for the general public.

Recent publications have put forth new charts of WCT as a function of air temperature and wind speed as recorded at 10 m height. Quayle has composed graphs to show how the data from Bluestein and Zecher, Oszcewski, and Steadman compare with the original NWS chart. One typical graph is shown in Figure 3 for -6.7°C (20°F) air temperature. The Oszcewski and Steadman results have the warmest WCT, with Bluestein and Zecher's results somewhat midway between those and the NWS values. These comparative results, with all other measures warmer than the S & P values, are the same for all combinations of air temperature and wind speed. Regardless of which of these new charts is considered, it seems clear that the original NWS chart exaggerated the effect of the wind.

Development of the Current WCT Chart

As result of an Internet conference organized by Canada in the spring of 2000, most meteorological organizations recognized the need to improve the method of wind chill determination. The NWS convened a joint action group to study temperature indices (JAG/TI) and to make a recommendation on the WCT. The weather service has indicated its desire to implement any improvements within 2 years. In addition, the International Society of Biometeorology (ISB) has formed a task force to study temperature indices as applicable to the international community. Some members of the JAG/TI are also members of this task force. Two international meetings were held in 2001 to determine the appropriate way to deal with wind chill.

The international community will be studying temperature indices with particular concentration on the following issues:

1. Can a temperature index be developed for the entire range of heat exchange?
2. Will the index be valid for all climates, seasons, and scales?

Figure 3 Comparison of published wind chill temperature scales for 20°F air temperature.

3. Will the index be useful in forecasting weather and other applications?
4. Will the index be independent of personal characteristics such as clothing and work activity?

A question to be answered is whether the WCT should be utilized separately from an inclusive temperature index.

The JAG or TI group charged Osczevski and Bluestein to develop a new chart as a compromise between their original models. Human trials were conducted in Canada with 12 instrumented volunteers in a wind tunnel. This resulted in a more accurate determination of skin conduction resistance. The researchers then applied modern heat transfer theory to a model of a half-cylinder representing the face turned into the wind, with a new still air condition of 1.34 ms^{-1} , (4.8 km h^{-1}), a more realistic walking speed. Heat is conducted from the internal body temperature of 37°C through the skin and then leaves the skin by convection and radiation to the ambient air. As a worst-case situation, the person is assumed to be walking at 1.34 ms^{-1} into the wind.

Using the method of Churchill and Bernstein, the rate of heat loss for a given air temperature and wind speed can be determined; an iterative solution using progressive estimates of the skin temperature is required. A WCT is then determined that will yield this same heat loss rate under still air conditions. To prepare the WCT charts, a regression equation was developed to match the data points at increments of 5° and five speed differentials. These equations are shown with the resultant charts in [Figure 1](#). The WCTs herein are higher (warmer) than those of the original chart and are deemed to be more accurate. Note that a correction for wind speeds measured at 10 m elevations has been included.

The new WCT charts include a warning of frostbite by time of exposure under severe conditions. The warning is based on exposed skin reaching -4.8°C , at which the risk is for frostbite in at least 5% of a population. This is based on the work of Danielsson.

Introduction

A 'standard atmosphere' is a vertical description of atmospheric temperature, pressure, and density that is usually established by international agreement and taken to be representative of the Earth's atmosphere. The first 'standard atmospheres' established by international agreement were developed in the 1920s primarily for the purposes of pressure altimeter calibrations and aircraft performance calculations. Later, some countries, notably the United States, also developed and published 'standard atmospheres.' The term 'reference atmosphere' is used to identify vertical descriptions of the atmosphere for specific geographical locations or globally. These were developed by organizations for specific applications, especially as the aerospace industry began to mature after World War II. The term 'standard atmosphere' has in recent years also been used by national and international organizations to describe vertical descriptions of atmospheric trace constituents, the ionosphere, aerosols, ozone, atomic oxygen, winds, water vapor, planetary atmospheres, and so on.

A standard unit of atmospheric pressure is defined as that pressure exerted by a 760 mm (or 29.22 inch) column of

mercury at standard gravity at 45.5425° N latitude and sea level (9.80665 m s^{-2}) at a temperature of 0 °C (32 °F). The recommended unit for meteorological use is 1013.25 hPa (1 hPa = 1 mb). Standard temperature is used in physics to indicate a temperature of 0 °C (32 °F), the ice point, and a pressure of one standard atmosphere (1013.25 hPa). In meteorology, the term standard temperature has no generally accepted meaning, except that it may refer to the temperature at zero pressure–altitude in the standard atmosphere (15 °C) with a density of 1.2250 g m^{-3} . The standard sea-level values of temperature, pressure, and density that have been used for decades are temperature of 288.15 K, 15 °C, or 59 °F; pressure of 1013.25 mb, 760 mmHg, or 29.22 inches Hg; and density of $1.225.00 \text{ g m}^{-3}$ or $0.076474 \text{ lb ft}^{-3}$.

In 1925, the US National Advisory Committee for Aeronautics (NACA) Standard Atmosphere (or US Standard Atmosphere) was published. In 1952, the International Civil Aeronautical Organization (ICAO) produced the ICAO Standard Atmosphere, and in 1964 an extension to 32 km. Subsequently, there have been a succession of 'Standard and Reference Atmospheres,' some extending to altitudes above

T = kinetic temperature; p = pressure; d = mass density; mfp = mean free path; part. speed = particle speed; coll. freq. = collision frequency; mean mol. wt = mean molecular weight; therm. cond. = thermal conductivity; scale ht = scale height; spec. wt = specific weight; and spec. heat = specific heat.

CIRA: COSPAR (Committee on Space Research) International Reference Atmosphere; ISO: International Organisation for Standardization; GRAM: Global Reference Atmosphere Model; AFGL: Air Force Geophysics Laboratory; NASA: National Aeronautics and Space Agency; MSIS: Mass Spectrometer and Incoherent Scatter; and NRL: Naval Research Laboratory.

Reproduced from Vaughan, W.W., Johnson, D.L., Justus, C.G., et al., 1996. Guide to Reference and Standard Atmosphere Models, Document ANSI/AIAA G-003A-1996. American Institute of Aeronautics and Astronautics, Reston, VA.

1000 km, produced by the US Committee on Extension to the Standard Atmosphere (COESA), Committee on Space Research (COSPAR), Comitet Standartov (USSR), International Standardization Organization (ISO), US Air Force Research and Development Command (ARDC), US Range Commanders Council (RCC), and US National Aeronautics and Space Administration (NASA), plus others.

In 1975, the International Standards Organization published a Standard Atmosphere for altitudes from -2 to 50 km that is identical to the ICAO Standard Atmosphere from -2 to 32 km. Subsequently, the ISO published in 1982 a family of five Reference Atmospheres for Aerospace Use for altitudes up to 80 km and latitudes of 15° N, 30° N, 45° N, 60° N, and 80° N.

Figure 1 provides an illustration of the temperature–height profiles to 100 km of the COESA US Standard Atmosphere, 1976, and the lowest and highest mean monthly temperatures obtained for any location between the Equator and Pole. The portion of the US Standard Atmosphere up to 32 km is identical with the ICAO Standard Atmosphere, 1964, and below 50 km with the ISO Standard Atmosphere, 1973.

For altitudes above approximately 100 km, significant variations in the temperature, and thus density, occur due to solar and geomagnetic activity over the period of a solar cycle. Variations in the temperature–height profiles for various degrees of solar and geomagnetic activity are presented in **Figure 2**. Profile (a) gives the lowest temperature expected at solar cycle minimum; profile (b) represents average conditions at solar cycle minimum; profile (c) represents average conditions at a typical solar cycle maximum; and profile (d) gives the highest temperatures to be expected during a period of exceptionally high solar and geomagnetic activity.

Currently, some of the most commonly used Standard and Reference Atmospheres include the following:

- ICAO Standard Atmosphere, 1952/1964;
- ISO Standard Atmosphere, 1973;
- US Standard Atmosphere, 1976;
- COSPAR International Reference Atmosphere; (CIRA), 1986; and
- NASA Global Reference Atmosphere Model (GRAM), 1999.

In 1996, the American Institute of Aeronautics and Astronautics (AIAA) published a *Guide to Reference and Standard Atmosphere Models*. This document provides information on the principal features for a number of global, regional, middle atmosphere, thermosphere, test range, and planetary atmosphere models. Summary information on these reference and standard atmosphere models is given in **Table 1**.

Synopsis

Aerosols are essential for cloud formation. Every cloud droplet needs an aerosol particle, called cloud condensation nucleus, for activation. Likewise ice crystals either form on a subset of aerosol particles that act as ice nuclei or form by homogeneous freezing of supercooled solution drops. Anthropogenic aerosols cause an indirect radiative forcing by modifying cloud properties. This indirect radiative forcing has uncertainties that are larger than for any other forcing.

Introduction

Aerosols are essential for cloud formation. Every cloud droplet needs an aerosol particle, called cloud condensation nucleus (CCN), for activation. Likewise ice crystals either form on a subset of aerosol particles that act as ice nuclei (IN) or form by homogeneous freezing of supercooled solution drops (liquid aerosols that took up water). In the absence of aerosols, several 100% relative humidity (RH) would be necessary for cloud droplets to form by homogeneous nucleation from supersaturated water vapor. Due to the ubiquitous presence of CCN, the RH in water clouds hardly exceeds 101%. The situation is different for ice clouds because IN are sparse, and formation of cirrus clouds is dominated by homogeneous freezing of solution droplets. This takes place at relative humidities below 100% with respect to water but well above 100% with respect to ice (at $-60\text{ }^{\circ}\text{C}$ the RH for homogeneous freezing is 150%). At the same time, removal of aerosols by clouds and precipitation is the largest sinks for aerosols with diameters $<1\text{ }\mu\text{m}$. Thus the lifetime of aerosols is strongly linked to that of clouds.

Atmospheric Aerosols

An aerosol is defined as a disperse system with air as the carrier gas and a solid or liquid disperse phase or a mixture of both. In atmospheric science, it is common to use the term ‘aerosol’ just for the solid or liquid particles and neglect the carrier gas. Aerosol particles range from 1 nm to several hundred micrometers in diameter. Aerosol particles can be as large as cloud droplets or ice crystals. Whereas cloud droplets or ice crystals only occur in isolated patches, aerosol particles, especially the smaller ones, are rather homogeneously mixed in the atmosphere.

Aerosols have a variety of different formation mechanisms. They are divided into primary and secondary particles. Primary particles are already emitted as aerosol particles (either liquid or solid) into the atmosphere. Primary aerosols can result from bulk-to-particle conversion, such as wind blown dust from arid regions, or emissions of pollen and spores by plants or can originate from combustion processes. Mineral dust is mainly emitted in arid regions. Its emission rate depends on wind speed, soil moisture and the bare soil fraction. Sometimes

liquid-to-particle conversion is used for the formation of sea-salt aerosols. Sea-salt aerosols originate from bursting of air bubbles that reach the ocean surface. The bursting bubbles leave water droplets containing sea salt behind. Upon evaporation of the water droplet, a sea-salt particle is released to the atmosphere. Primary aerosols are mainly large particles of natural origin and thus account for the largest aerosol mass in the atmosphere.

Primary particles are distinguished from secondary aerosols, which form within the atmosphere from precursor substances (gases) by gas-to-particle conversion and form small aerosol particles. Examples of secondary aerosols in the atmosphere are sulfates, nitrates and secondary organic aerosols. Secondary particles have both natural and anthropogenic sources. Gas-to-particle conversion requires a nucleation process because a new phase (liquid or solid) is formed from a supersaturated gas phase. The most common form of particle nucleation is binary nucleation where the aerosol forms from two gas phase precursors. Homogeneous self-nucleation of a single species does not take place in the atmosphere as that would require that the vapor pressure of a single species is supersaturated. For binary nucleation to take place, each species can be subsaturated if the mixture is supersaturated. A prominent example of binary nucleation is the reaction of n moles water vapor H_2O (g) with m moles of gaseous sulfuric acid H_2SO_4 (g), resulting in the nucleation of liquid sulfuric acid aerosol particles: $(\text{H}_2\text{O})_n(\text{H}_2\text{SO}_4)_m$ (aq), where aq denotes the aqueous phase.

A schematic representation of aerosol binary nucleation of H_2O and H_2SO_4 with subsequent growth to larger sizes is shown in Figure 1. The first step is that a cluster of H_2O and H_2SO_4 is formed in the gas phase. Once the cluster exceeds its critical size, nucleation occurs and a stable sulfuric acid aerosol particle is formed. The critical size of a cluster is the size at which the droplet can exist in equilibrium with its vapor phase. Once the particle is formed, also other species, such as organics of low volatility can condense onto the particle and participate in its growth. Low volatility is

necessary as otherwise the organics would not remain in the condensed phase and evaporate again. The aerosol particle also grows by coagulation with other particles. The newly formed aerosol particle needs to increase 1–2 orders of magnitude in size before it can act as a CCN and be involved in cloud formation.

Hygroscopic Growth

Condensation of water vapor on aerosol particles (water uptake) is important for aerosol particles with an affinity for water vapor, i.e., for hydrophilic or hygroscopic aerosols, such as sulfate, nitrate, sea-salt, or mineral dust particles. This swelling of aerosol particles needs to take place before aerosol particles can act as CCN. Water uptake can cause a phase change if the soluble aerosol was solid before. If the aerosol is already liquid, then water uptake just leads to further growth and dilution of the salt solution. The phase change of the solid soluble aerosol to a liquid aerosol is called deliquescence and does not require a nucleation process. The opposite process, the formation of a solid aerosol, is called efflorescence or crystallization and requires a nucleation process. Nucleation requires overcoming an energy barrier, which can only be achieved if prior to nucleation the nucleating substance is in a supersaturated state as in the case of binary nucleation of H_2O and H_2SO_4 .

The growth of the aerosol is described in terms of the growth factor, which is the ratio of the actual aerosol diameter to its diameter at 0% RH. It is only defined for RHs below 100%. Some aerosols such as sulfuric acid (H_2SO_4) remain liquid at all relative humidities (Figure 2) at atmospheric temperatures and pressures and just change their size according to RH. Other aerosols, predominantly salts such as ammonium sulfate or ammonium bisulfate, change their phase. At which RH this phase change occurs depends on the direction of the change in RH. In case of ammonium sulfate, the sudden increase in diameter by 50% occurs at 80% RH. This increase in

Figure 1 Schematic representation of the nucleation and subsequent growth process for atmospheric binary homogeneous nucleation of H_2SO_4 and H_2O . Once stable clusters are formed, also other substances such as organics can take part in the growth process. Particles may grow to sizes large enough to act as CCN on which cloud droplets may form eventually. Figure reproduced with courtesy from Curtius, J., 2006. Nucleation of atmospheric aerosol particles. *C. R. Phys.* 7, 1027–1045.

Figure 2 Water uptake of sulfuric acid (H_2SO_4), ammonium bisulfate (NH_4HSO_4), and ammonium sulfate ($(\text{NH}_4)_2\text{SO}_4$) aerosols expressed in terms of their growth factor, which is the ratio of the actual diameter D_p to the dry diameter at 0% RH (D_{p0}), as a function of RH. Figure reproduced with courtesy from Seinfeld, J.H., Pandis, S.N., 1998. *Atmospheric Chemistry and Physics: From Air Pollution to Climate Change*. Wiley, 1326 pp.

diameter goes hand in hand with a phase change from solid to liquid and is referred to as the deliquescence relative humidity. Here the salt dissolves in water.

If RH is decreased, ammonium sulfate remains in the liquid phase until 40% RH, where it suddenly solidifies. This RH is called the crystallization relative humidity. The growth factor of ammonium sulfate exhibits a hysteresis, meaning the value of the growth factor is not unambiguously determined by RH, but depends also on the history of the particle. Between 40 and 80% RH the liquid phase of ammonium sulfate is metastable. Energetically, the aerosol would prefer to be in the solid state but it is prevented from doing so because it first needs to surpass the energy barrier for nucleation.

Cloud Droplet Formation

Cloud droplet formation is not a nucleation process because cloud droplets form on soluble or hydrophilic aerosol particles, which already have taken up large amounts of water below 100% RH. Cloud formation is best described by the Koehler equation:

$$e^*(r)/e_s(\infty) = S = 1 + a/r - b/r^3 \quad [1]$$

The Koehler equation describes the ratio between the equilibrium vapor pressure over a solution droplet $e^*(r)$ with radius r to the saturation vapor pressure over a plane surface of water $e_s(\infty)$ with a and b as described below. $e_s(\infty)$ depends exponentially on temperature (T) as described by the Clausius–Clayperon equation:

$$de_s/dT = L_v e_s / (R_v T^2) \quad [2]$$

where R_v is the specific gas constant of water vapor ($R_v = 461.5 \text{ J K}^{-1} \text{ kg}^{-1}$) and L_v is the latent heat of vaporization. The Koehler equation has two contributions, the increase in vapor pressure that is associated with the formation of the surface (Kelvin equation) and the decrease in vapor pressure due to soluble substances in water (Raoult's law). The Kelvin equation is given as:

$$e_s(r)/e_s(\infty) = S = \exp(2\sigma/(r \rho_w R_v T)) \quad [3]$$

where σ is the surface tension between water and air. At 273.2 K, σ is 0.0756 N m^{-1} and ρ_w , the water density, is 1000 kg m^{-3} . The terms of the Kelvin equation other than the radius of the droplet are summarized in term a of the Koehler equation: $a = 2\sigma/(r \rho_w R_v T)$. Kelvin's equation describes that the equilibrium vapor pressure is larger over a droplet with radius r than over a plane or bulk surface. It inversely relates the critical radius for droplet formation to the necessary supersaturation. At $S = 1.01$, a typical value found in the atmosphere, the critical radius of the droplet needs to be $0.12 \text{ }\mu\text{m}$. This can never occur by chance as it involves 0.25 million water vapor molecules. A more reasonable number of 20 water vapor molecules forming a cluster with a critical radius of 0.5 nm requires a saturation ratio S of 10, i.e., an RH of 1000%, which does not exist in Earth's atmosphere.

The second contributor to the Koehler equation, Raoult's law, is given for a plane surface of water as follows:

$$e^*(\infty)/e_s(\infty) = n_0/(n + n_0) \quad [4]$$

where e^* is the equilibrium vapor pressure over a solution consisting of n_0 water molecules and n solute molecules. This equation shows that if the vapor pressure of the solute is less than that of water and if the total number of molecules remains constant, the vapor pressure over the solution is reduced in proportion to the amount of solute present. The vapor pressure reduction arises from solute molecules at the surface that limit the exchange of water molecules between the water surface and the overlying vapor to those places where water molecules occupy the surface. For dilute solutions and applied to droplets of size r , Raoult's law can be approximated as:

$$e^*(r)/e_s(r) = 1 - b/r^3, \quad \text{where } b = 3 i M_s m_w / (4\pi m_s \rho_w) \quad [5]$$

The competition between Kelvin's equation and Raoult's law is summarized in the Koehler equation. **Figure 3** displays the Koehler curves, i.e., the equilibrium vapor pressure as a function of the droplet radius, for droplets containing different amounts of salt. Note that every salt particle with a dry radius r_d has its own individual Koehler curve. Because

Figure 3 Koehler curves for NaCl (solid lines) and $(\text{NH}_4)_2\text{SO}_4$ (dashed lines) for droplets originating from salt particles with different dry radii r_d . In addition, the Kelvin curve (common for all particles) is shown in olive and Raoult's law for $(\text{NH}_4)_2\text{SO}_4$ as dot-dashed lines.

Raoult's law applies to the droplet volume, it dominates over the Kelvin effect, that depends on droplet size, at small radii and lowers the equilibrium vapor pressure at small radii below $S = 1$. The Kelvin effect is negligible for droplets larger than $1\ \mu\text{m}$ where all curves approach $S = 1$.

The peak in the saturation ratio called critical saturation ratio (S_c) and the corresponding critical radius (r_c) can be obtained by differentiating the Koehler equation with respect to r and setting the derivative to 0:

$$r_c = (3b/a)^{1/2}; \quad S_c = 1 + (4a^3/27b)^{1/2} \quad [6]$$

S_c of a specific Koehler curve is the minimum saturation ratio that is required for the corresponding solution droplet to grow to cloud droplet size. Theoretically, it could grow even larger, but the growth becomes increasingly slower the larger the droplet and more efficient growth mechanisms such as growth by collision-coalescence with other droplets will take over (see **Clouds and Fog: Cloud Microphysics**). If the droplet has grown to $r > r_c$ it is called an activated droplet. All droplets that have a critical saturation ratio $S_c < S$, where S is the supersaturation reached in the ambient air, can thus be activated. If $S < S_c$, a deliquesced salt particle can only grow to the radius at which the Koehler curve takes the value S .

The Koehler curve represents equilibrium conditions and therefore has some limitations of its applicability. Large particles have large equilibrium radii and may have insufficient time to grow to their equilibrium size in clouds that do not last long, such as convective clouds. **Figure 3** shows that the higher S , the more and the smaller aerosols can be activated. It also shows that the largest aerosols are the best CCN because they require the smallest supersaturations to be activated. However, there are only few of them available. Also, because the diffusional growth depends inversely on the size of the droplets with the smallest droplets growing the fastest (see **Clouds and Fog: Cloud Microphysics**), the large aerosols may not reach their critical size by diffusional growth. On the other hand, the smallest aerosols require higher supersaturations to activate than exist in the atmosphere. Thus, these aerosols are not efficient for cloud formation either. Mainly accumulation and coarse mode, and partly Aitken mode aerosols act as CCN and get activated into cloud droplets.

Ice Crystal Formation

Once a cloud extends to altitudes where the temperature is below $0\ ^\circ\text{C}$, ice crystals may form either by freezing of a cloud droplet or by direct deposition of the vapor to the solid phase. Both, freezing of cloud droplets and deposition of vapor to the solid phase, are nucleation processes because a stable cluster of the new ice phase has to form within the parent phase (vapor or liquid). Both homogeneous and heterogeneous nucleations are possible for the formation of ice crystals and have been observed in the atmosphere. Homogeneous freezing of liquid aerosols is the dominant freezing process in cirrus clouds. These liquid aerosols, also called supercooled solution droplets, are in equilibrium with the ambient RH below 100% with respect to water, but are not activated as cloud droplets. Heterogeneous ice nucleation, which requires the presence of

an IN, is the dominant ice nucleation process in mixed-phase clouds. Mixed-phase clouds are clouds that exist between 0 and $-40\ ^\circ\text{C}$ and consist of a mixture of supercooled cloud droplets and ice crystals.

IN are aerosol particles that provide a surface onto which water molecules can stick, bond together, and form aggregates with an ice-like structure. Differently from CCN, only a small fraction (one in $100\,000$ – $1\,000\,000$) of all aerosol particles can serve as IN at temperatures warmer than $-40\ ^\circ\text{C}$. Therefore, the criteria for aerosols to act as IN are less well understood as compared to the CCN ability of aerosol particles.

Homogeneous deposition nucleation of vapor to form ice crystals is analogous to homogeneous cloud droplet nucleation. Also here the vapor pressure increase over an ice sphere is increased as compared to bulk ice, the more the smaller the crystal is. It can thus be described with Kelvin's equation (see above) except that the parameters related to liquid water need to be replaced with those of ice. Homogeneous deposition nucleation is even less likely than homogeneous cloud droplet formation because of the higher surface tension between ice and air than between water and air and because the ice density is lower than the water density. Both differences increase the vapor pressure over an ice sphere more than that over a cloud droplet (see **eqn [3]**).

On the other hand, homogeneous freezing of ice within a liquid drop is observed in the atmosphere. It occurs when statistical fluctuations of the molecule arrangement of water produce a stable, ice-like structure, called ice germ. The formation of the surface of an ice-like structure requires an energy barrier to be overcome analogous to the crystallization of salts discussed above. If the ice germ exceeds the energy barrier for nucleation, it can grow spontaneously and cause the entire droplet to freeze. Experimental data on the freezing of pure water show that cloud droplets below a radius of $5\ \mu\text{m}$ will freeze spontaneously at temperatures below $-38\ ^\circ\text{C}$ **Pruppacher and Klett (1997)**. Larger droplets freeze at slightly warmer temperatures. Homogeneous freezing of pure water only occurs at or above water saturation (**Figure 4**) since only at these conditions pure water droplets can exist in equilibrium.

In cirrus clouds, the RH is not high enough to activate cloud droplets. The RH is, however, high enough for unactivated solution droplets to exist, which also can freeze homogeneously. Homogeneous freezing of solution droplets is the dominant pathway of ice crystal formation in cirrus clouds. Solution droplets refer to sulfuric acid or other liquid aerosols that have taken up water. The presence of salt causes the freezing point to be colder than that for pure water (freezing point depression). If the RH is not sufficiently high, the salt is too concentrated inside the solution droplets for freezing to occur. Therefore, homogeneous freezing of solution droplets occurs only at or above the dashed line that starts at $-35\ ^\circ\text{C}$ in **Figure 4**. Homogeneous freezing of solution droplets deviates from the water saturation more and more with decreasing temperature below $-35\ ^\circ\text{C}$ because solution droplets can freeze with higher salt concentrations and concentrated droplets can exist in equilibrium at lower relative humidities.

Heterogeneous freezing initiates freezing with the help of an IN. An IN favors freezing over homogeneous freezing because it reduces the energy barrier to the formation of a critical ice germ.

Figure 4 Schematic of the main freezing processes as a function of temperature and the saturation ratio with respect to ice (Hoose, C., Möhler, O., 2012. Heterogeneous ice nucleation on atmospheric aerosols: a review of results from laboratory experiments. *Atmospheric Chemistry and Physics* 12, 9817–9854). The solid line refers to saturation with respect to water. The dashed line that starts at -35°C refers to the homogeneous freezing line of solution droplets according to Koop, T., Luo, B., Tsias, A., Peter, T., 2000. Water activity as the determinant for homogeneous ice nucleation in aqueous solutions. *Nature* 406, 611–614.

Four heterogeneous freezing modes are distinguished in the literature (Figure 4). Immersion freezing refers to the freezing that is initiated from within the droplet. It requires that the IN is already immersed in the cloud droplet at warmer temperatures. Upon cooling freezing is initiated (Figure 4). Sometimes condensation freezing is distinguished from immersion freezing. It is thought that condensation freezing refers to a different pathway in which the aerosol containing the IN starts from subsaturated conditions. When water saturation is exceeded, a liquid phase is formed, which is large enough for an ice germ to form inside of it. This ice germ within the liquid phase then initiates the freezing (Figure 4). Contact freezing refers to the collision of an IN with a supercooled cloud droplet. It requires the presence of a cloud droplet and is therefore shown on the water saturation line in Figure 4. Deposition nucleation refers to the direct deposition of vapor onto an IN. It requires that the air is supersaturated with respect to ice ($S_i > 1$). Deposition nucleation is important for cirrus clouds, when vapor is deposited for instance onto mineral dust particles that act as IN. It does not seem to be important for mixed-phase clouds, because observations reveal that the majority of clouds with 0 and -40°C have liquid water droplets at the cloud base, suggesting that immersion or contact freezing are the most important freezing mechanisms in mixed-phase clouds.

The criteria for aerosols to act as IN are thought to be (1) solid state, (2) size, (3) lattice structure, (4) molecular bindings with water, and (5) active sites. There is, however, some dispute about the importance of each of them and how many criteria are required. In order to reduce the energy barrier of heterogeneous nucleation below that of homogeneous nucleation, an ice germ has to form on a solid surface. A solid surface is necessary and is readily fulfilled for the most commonly occurring IN such as mineral dust, biological particles, and

soot. But also crystalline ammonium sulfate and some organics that are solid at certain conditions of temperature and RH can act as IN. Similarly to CCN also for IN size matters. The larger the IN surface, the larger the probability that a critical cluster forms on it. Also the larger the IN surface, the larger the probability that a good active site (see below) can be found onto it. A crystalline structure, which is similar to the ice lattice, is preferable for an IN. This is the case for silver iodide, which has been found to nucleate ice at temperatures up to -6°C . However, organics and mineral dust particles can also act as IN, although their lattice structures differ from that of ice. Thus, it is conceivable that the ability to form hydrogen bonds with water is more important than the lattice structure. Active sites refer to imperfections on the surface of the IN. They can be thought of as crevasses or steps in the lattice structure. The critical ice germ needs a smaller mass to reach the critical ice germ radius in crevasses or in corners of steps than on a plane surface, i.e., the energy barrier is particularly small in imperfections. Once ice is formed, additional water molecules can readily be attracted. Active sites are also used as an explanation why at a given temperature, RH and size of a given aerosol compound, only a fraction of a given aerosol species acts as IN. In summary, some combinations of size, lattice structure, molecular binding, and low interfacial energy with ice as promoted by active sites accounts for the IN ability of a substance.

Radiative Forcing of Anthropogenic Aerosols due to Aerosol–Cloud Interactions

Aerosol particles can affect the climate by scattering and absorption of radiation and thus exert a radiative forcing due to aerosol–radiation interactions (RF_{ari}). In addition, aerosol particles can cause a radiative forcing by acting as CCN and IN, i.e., due to aerosol–cloud interactions (RF_{aci}). Both RF_{ari} and RF_{aci} have partially offset the greenhouse gas warming since preindustrial times. Whereas radiative forcing means that the atmospheric state remains constant, the cloud lifetime, coverage, or phase may change when perturbed by aerosols from anthropogenic activity. Adjustments in clouds occur on much faster time scales than the warming due to greenhouse gases. Therefore, it has been proven useful to also introduce an effective radiative forcing where macroscopic adjustments (cloud height, lifetime, and cover) to microphysical perturbations are considered as well.

RF_{aci} refers to an increase in cloud droplet number concentration resulting from an increase in anthropogenic aerosols. If the cloud water cloud remains constant, then the surface area of the cloud is larger and therefore more solar radiation is reflected back to space. This effect was previously referred to as the Twomey effect. RF_{aci} is reported as the global annual mean change in the net top-of-the-atmosphere radiation since preindustrial times due to the aerosol-induced changes in cloud optical properties. RF_{aci} has been estimated mainly from global climate models to have caused an RF_{aci} of -0.7 W m^{-2} with a range between -0.3 and -1.8 W m^{-2} (Forster et al., 2007). Evidence for RF_{aci} can be seen in so-called ‘ship tracks’ that leave behind white lines in satellite pictures. They are caused by the increase in albedo due to the injection of pollution aerosols from the ships that increase CCN and thus the number of cloud droplets. However, ship tracks cannot be

seen all the time because of counteracting processes. This includes a faster evaporation of the more but smaller cloud droplets or increased entrainment of warm dry air from above the boundary layer into these ship tracks. Buffering processes are also the reason why ERF_{aci} is even more uncertain than R_{Faci} itself. The total anthropogenic aerosol effect due to aerosol–radiation and aerosol–cloud interactions (ERF_{aci-ari}) has been estimated from global climate models and satellite studies and amounts to -1.2 W m^{-2} with a range between -0.2 and -2.3 W m^{-2} since preindustrial times (Denman et al., 2007). Not only are the adjustment processes less well known, but they are also not well represented or are even missing in current climate models (Stevens and Feingold, 2009).

One source of uncertainty is the ice phase. Compared to warm clouds and CCN activation, aerosol effects on mixed-phase and ice clouds are much less understood (Lohmann and Feichter, 2005). While there is a consensus that mineral dust particles are good IN because they initiate ice formation at rather warm temperatures/low supersaturations, studies disagree about the importance of carbonaceous aerosols to act as IN (Hoose and Möhler, 2012). Terrestrial biogenic aerosols such as bacteria, pollen, and fungal spores have been identified as being good IN (Hoose and Möhler, 2012), and there are indications that marine planktonic diatoms also act as IN. These biological IN initiate ice formation at higher temperatures than mineral dust, but it is not clear yet if sufficiently large concentrations can be found in the atmosphere to substantially influence mixed-phase and ice clouds. Consequently, the contribution of anthropogenic emissions on IN concentrations is not yet determined. If more IN exist due to anthropogenic activity, supercooled clouds would freeze more readily. Because the vapor pressure of ice is lower than that of water, the ice crystals would grow at the expense of the cloud droplets (see Clouds and Fog: Cloud Microphysics). Glaciated clouds precipitate more readily which decreases their lifetime. This could partly offset the aerosol effect on warm clouds. However, anthropogenic emissions may deactivate IN due to coating with soluble material, such as sulfuric acid. Whether the faster glaciation or the deactivation

of anthropogenic IN is more important is still an open question. It differs in different climate models and is therefore partly responsible for the large range in ERF_{aci-ari} (Lohmann et al., 2010). In summary, aerosol–cloud interactions are not well known yet and their radiative and adjusted forcings will remain uncertain for some time to come.

Synopsis

A broad overview is given on physical and chemical properties and processes of tropospheric aerosol particles. Primary and secondary, natural and anthropogenic particle sources are described followed by a description of key physical properties and processes, such as particle size distribution, formation, and removal processes. Particle properties governing particle water uptake and the formation of cloud droplets and ice crystals are described. The particle composition is discussed, with an emphasis on the organic aerosol fraction, especially secondary organic aerosols. Concepts are presented to describe heterogeneous reactions between atmospheric trace gases and aerosol particles.

Introduction

An aerosol is defined as an ensemble of solid or liquid particles suspended in a gas, e.g., in air. In atmospheric science the term ‘aerosol’ is often used to describe the particles of an aerosol only, which can lead to confusion. Aerosol particles have been recognized since decades to be of key importance for many processes throughout the atmosphere: they critically influence directly the radiative balance of the Earth’s atmosphere, affect cloud formation, and are also one of the main air pollutants contributing to a variety of respiratory and cardiovascular diseases. Despite this importance, aerosol particles are relatively poorly characterized with respect to their concentration, temporal and spatial distribution, and physical and chemical properties. This large uncertainty is mainly caused by the variable and insufficiently understood sources, formation and transformation processes, and composition of atmospheric particles.

This article focuses on tropospheric particle properties and processes and does not discuss particles present at higher atmospheric altitudes.

Aerosol Particle Sources

In the lower atmosphere, the troposphere, there are a large number of aerosol particles sources, which are usually divided into two main categories: natural and man-made (anthropogenic). Distinguishing between natural and anthropogenic particle sources is especially important when technical or regulatory measures are considered to reduce atmospheric particle concentrations and their effects in the atmosphere because only anthropogenic sources can be effectively influenced. Both categories can be subdivided into primary particles, defined as particles directly emitted into the atmosphere, and secondary particles, defined as particles (or particle mass) that are formed within the atmosphere through physical or chemical processes. The identification of secondary particles is especially challenging because this requires an accurate knowledge of the atmospheric chemistry leading to the formation of the compounds that partition from the gas to the particle phase. Due to the highly complex chemical composition of tropospheric particles this is currently one of

the major factors limiting our understanding of particle effects in the atmosphere.

Natural Particle Sources

Main primary natural sources are sea salt, mineral dust, primary biological material, and volcanic particles. Mineral dust particles, emitted predominantly in deserts and semiarid regions, are the most abundant particle type (on a mass basis) in the atmosphere on a global level (Textor et al., 2006). Mineral dust particles can be transported from major source regions such as the Sahara and Gobi desert, the Arabian Peninsula or the U.S. Southwest during large dust storms over long, intercontinental distances. For remote open ocean areas, mineral dust deposition are a significant nutrient source, especially of trace elements such as iron or phosphorous. Equally important on a global level are sea-salt particles, which are generated through bubble bursting processes and breaking waves at the sea surface and are strongly correlated with wind speed.

Primary biological particles include a wide variety of particles such as pollen, fungal spores, bacteria, and plant debris and in marine environments also organic material present in the ocean surface layer (Despres et al., 2012). Primary particles have been identified as efficient cloud condensation and ice nuclei and therefore may significantly affect particle–cloud interactions. However, the number or mass of primary organic particles is difficult to quantify mainly due to their low concentration and diversity. Volcanic primary particle emissions are by nature sporadic and are composed of SiO_2 , Al_2O_3 , and Fe_2O_3 . Due to the rather large particle size, their effects are mostly local or regional.

Natural, secondary particles are formed from a number of nitrogen- and sulfur-containing and also organic source gases. On a global scale dimethyl sulfide (DMS) is an important precursor, which is emitted by marine phytoplankton. In the atmosphere DMS is oxidized to SO_2 and finally to sulfuric acid. Gaseous sulfuric acid forms aerosol particles very quickly or condenses onto existing particles due to its low vapor pressure. Nitrate is another important inorganic particle component, which is formed mainly through oxidation of NO_x and N_2O . Lightning and soil emissions (bacterial activities) are the main sources of these precursors. The largest natural secondary

particle fraction is formed from gaseous organic precursors such as terpenes and sesquiterpenes, which are emitted by plants. Upon oxidation in the atmosphere, mainly with OH, O₃, or NO₃, a large range of reaction products is formed. Some of these reaction products with low vapor pressures condense onto particles. The chemical composition of secondary organic particles is highly complex and several hundred compounds can be found in secondary organic aerosol particles formed from one single organic precursor gas (Reinhardt et al., 2007).

Anthropogenic Particles Sources

Primary particles generated due to human activities include biomass burning, fossil fuel combustion, and industrial activities. Although wild fires can have purely natural causes, they are often linked to anthropogenic activities. In recent years it was also recognized that a significant fraction of the organic particle mass present in the atmosphere is due to biomass burning from residential heating and cooking activities, not only in developing but also in industrialized countries. Soot (i.e., graphite-like carbon), organic material, and inorganic salts are the main components of biomass burning particle and can vary significantly depending on the type of biomass and the burning conditions: initial combustion stages and poor ventilation conditions can cause orders of magnitude larger particle emissions than well established flaming conditions. Fossil fuel combustion is also a significant source of soot and organic particle mass in the atmosphere. In addition, a number of large-scale industrial processes can emit significant particle mass into the atmosphere such as mining, cement manufacturing, or metal processing industry. These sources are often of local importance.

Secondary, anthropogenic sources include inorganic and organic components that are formed via gas–particle conversion processes. Fossil fuel consumption and incomplete combustion as well as agricultural and industrial activities are the major sources. The main inorganic source gases for anthropogenic secondary particle mass are NO_x, SO₂, and NH₃, emitted by combustion processes (NO_x, SO₂) and agricultural activities (NH₃). Their oxidation products such as nitrate, sulfate, and ammonium account for roughly half the tropospheric aerosol particle mass (Jimenez et al., 2009). Similarly, oxidation of small, gaseous aromatic compounds leads to the formation of low-volatility oxidation products, which contribute to the organic aerosol mass (see also Section Chemical Composition).

Physical Properties

Size Distribution

Aerosol particles in the atmosphere usually cover a size range of several orders of magnitudes, from about 1 nm to 100 μm. These limits are not based on a rigorous concept but are often operationally defined and measured size distributions depend on and vary with analyses techniques. Below this size range particles are usually described as clusters as they are composed of only a limited number of molecules. The particle size distribution is usually divided into fine mode particles, consisting of nucleation mode (diameter <10 nm) and Aitken

mode particles (<100 nm), accumulation mode particles (100 nm–2 μm), and coarse-mode particles (>2 μm), which includes cloud droplets. The maximum in the number size distribution in urban areas is generally found in the nucleation mode. However, these smallest particles contribute only very little to the total aerosol surface or mass (Figure 1). The high number concentration observed in the nucleation mode particles in urban areas are mostly due to traffic-related sources. The maximum surface area, which is the important parameter for light scattering and for many heterogeneous reaction rates, usually lies in the accumulation mode. The total particle number concentration varies greatly in the troposphere with <20 particles cm⁻³ for the polar regions and >10⁵ particles cm⁻³ for an urban aerosol. The number concentration of the nucleation mode particles becomes generally less important at location far away from anthropogenic sources. The number size distribution of marine or desert aerosol is dominated by coarse-mode particles.

For air monitoring purposes, particle mass is usually measured for particles with a size smaller than 2.5 μm or 10 μm (abbreviated as PM_{2.5} and PM₁₀, respectively). This is mainly motivated by the size-dependent deposition of inhaled particles within the respiratory tract, where only particles smaller than 10 μm reach bronchia and lower parts of the lung where it is assumed that they cause most harm. Epidemiological studies

Figure 1 Idealized particle number (a), surface (b), and volume (c) size distribution for an urban location. Nucleation mode particle clearly dominates the total particle number whereas the total volume is dominated by accumulation and coarse-mode particles. Finlayson-Pitts, B.J., Pitts, J.N., 2000. Chemistry of the Upper and Lower Atmosphere. Academic Press, San Diego.

show strong correlations between negative health outcomes such as respiratory diseases and PM_{2.5} or PM₁₀ and less clear effects if the total particle mass is considered (Dockery et al., 1993).

Formation Processes

In the smallest size fraction (nucleation mode), particles are formed via homogeneous nucleation, which describes the formation of new particles through gas-to-particle conversion. Particle nucleation proceeds via initial molecule clusters, which involve water and sulfuric acid and possibly basic compounds such as ammonia, organic amines, or other organic compounds. Under favorable conditions these clusters grow over time to aerosol particles with tens of nm diameter as illustrated in Figure 2, with a typical growth rate of about 1–20 nm h^{−1}. Low-volatility organic compounds are thought to be mainly responsible for the growth of clusters into accumulation mode particles. Particle nucleation is usually observed when the pre-existing particle surface area is low but observations have been also made under highly polluted conditions or in coastal areas where nucleation is initiated by iodine oxides formed from biological sources (Zhang et al., 2012).

Particles in the accumulation mode typically arise from either the partitioning of low-volatility gases onto existing smaller particles, or from coagulation of particles. Chemical modification (heterogeneous reactions) following condensation of semivolatile components from the gas phase onto existing particles is another process, which can increase the mass of accumulation mode particles. Gas phase compounds partitioning into the particle phase are mainly formed in gas phase oxidation reactions leading to reaction products with a lower vapor pressure resulting in the partitioning of these reaction products into the particle phase.

The largest size fraction (i.e., coarse-mode particles with diameters larger than about 2 μm) is mainly generated in mechanical processes. Industrial or traffic-related processes are the main anthropogenic sources but wind-blown dust is by far the largest source of coarse-mode particles on a global level.

Removal Processes

The concentration of nucleation mode particles with diameters <10 nm is rapidly reduced through coagulation, resulting in

a lifetime in the order of minutes for these smallest particles. The coagulation rate of particles with size 1 and 2 can be described by eqn [1]

$$\frac{dN_{1,2}}{dt} = -K_{1,2}N_1N_2 \quad K_{1,2} = \pi(d_1 + d_2)(D_1 + D_2) \quad [1]$$

where $K_{1,2}$ is the coagulation coefficient, D the diffusion constant, and d the particle diameter. Values for $K_{1,2}$ are given in Table 1 for a range of particle sizes. Most efficient coagulation is observed between small particles with a high diffusion constant and large particles with a high surface area.

The main removal process for accumulation mode particles is incorporation into cloud droplets and subsequent wet deposition. Wet deposition is also described as scavenging, which can be distinguished in in-cloud and below-cloud scavenging. The wet deposition rate of particles depends largely on the particle size and the chemical composition (see below).

Particles of all sizes also undergo dry deposition. The efficiency of this process is strongly size dependent. The flux of particle dry deposition to the ground, F , can be described as the product of the particle concentration, c , and the deposition velocity, v_g (eqn [2]).

$$F = v_g \cdot c \quad [2]$$

Particles below about 50 nm diameter behave essentially like gases with respect to dry deposition and are efficiently removed due to Brownian diffusion. Coarse-mode particles in

Table 1 Coagulation coefficients for particles of different sizes ($K_{1,2} \times 10^{-10} \text{ cm}^3 \text{ s}^{-1}$) under standard temperature and pressure

d_2 (nm) \ d_1 (nm)	0.01	0.1	1.0	10.0
0.01	67			
0.1	180	8.6		
1.0	1700	24	3.5	
10.0	16000	220	10.3	3.0

Figure 2 Particle nucleation. Evolution of the particle size distribution over the course of a day. A nucleation event is observed at a boreal forest site in Finland around midday. Particles grow through condensation over several hours to sizes of about 50 nm (Manninen, H.E., et al., 2009. Charged and total particle formation and growth rates during EUCAARI 2007 campaign in Hyytiälä. Atmospheric Chemistry and Physics 9, 4077–4089). The color code indicates the particle concentration at a particular size.

the range of 2–20 μm are mostly deposited due to inertial impaction and very large particles $>20 \mu\text{m}$ are removed due to gravitational settling (sedimentation). All the dry deposition processes are less effective for particles in the accumulation mode (50 nm–2 μm), and thus these particles have the longest atmospheric lifetime (i.e., minimum deposition velocity).

Water Uptake and Particle Phase

As mentioned above, incorporation of particles into clouds is one of the most efficient particle removal processes. In addition, particle–cloud interactions strongly affect the formation of clouds and precipitation and thus are key processes in the hydrological cycle. Via light scattering of clouds this also affects indirectly the radiative budget of the atmosphere.

The ability of a particle to take up water (hygroscopicity) and to grow eventually to a cloud droplet (cloud condensation nuclei) is mainly governed by the initial dry particle size, its chemical composition, and the relative humidity. The Köhler theory describes the water vapor pressure, S , over an aqueous droplet as described in eqn [3],

$$S = a_w \exp\left(\frac{2\sigma M_w}{RT\rho_w D}\right) \quad [3]$$

where a_w is the water activity, σ the surface tension of the surface–air interface, M_w the molecular weight of water, R the gas constant, T the temperature, ρ_w the density of water, and D the diameter of the droplet.

Two processes have to be considered to describe water uptake of particles, the Kelvin effect, the exponential term in eqn [3], describes the vapor pressure due to the curvature of the droplet surface compared to a flat interface and the Raoult's effect, which considers the influence from solutes, described by the water activity. The Kelvin effect tends to increase the water

vapor pressure while the Raoult's effect is mainly decreasing the water vapor pressure.

The effects of the hygroscopicity of solutes on the water activity can be described with a single parameter, κ , and is referred to as κ -Köhler theory (Petters and Kreidenweis, 2007). This allows modeling and comparing the hygroscopicity of single component particles with complex ambient particles of unknown composition.

At low droplet diameters the solute effect is often dominant (Figure 3). Droplet sizes in the raising part of the Köhler curve are stable and in equilibrium with the relative humidity of their surrounding atmosphere. If the relative humidity is higher than the critical supersaturation (i.e., the maximum of the Köhler curves in Figure 3) then a particle will grow to cloud droplet sizes of many micrometers as described by the unstable, decreasing part of the Köhler curve. The growth of a particle into a cloud droplet in a supersaturated atmosphere is called activation. Due to the Kelvin effect the critical supersaturation is higher for smaller particles and therefore larger particles are more efficiently activated to cloud droplets.

Particle hygroscopicity usually increases with increasing age of a particle in the atmosphere, which is due to condensation of oxidized, water-soluble gases onto the particle. This highlights the important link between chemical processing of particles and their physical properties. Inorganic salts such as ammonium sulfate or ammonium nitrate (both secondary particle compounds) are among the most hygroscopic components in atmospheric particles, whereas particles with high organic content or mineral dust particles have a low hygroscopicity.

Aerosol particles are essential not only for cloud droplet formation but also for ice crystal formation. At temperatures below about -15°C mineral dust particles are effective ice nuclei and some bacteria are efficient ice nuclei already at -3°C (Murray et al., 2012). Field experiments showed that

Figure 3 Köhler curves for ammonium sulfate particles with dry diameters of 50, 100, and 500 nm respectively, illustrating the dominant effect of the dry particle diameter on the water vapor supersaturation required to activate a particle to a cloud droplet. The dotted line indicates the Kelvin effect only.

these two particles types are the most abundant atmospheric ice nuclei (**Figure 4**) (Pratt et al., 2009).

Two processes are likely the most important ice nucleation processes in a cloud: contact freezing, which describes ice particle formation due to the collision of an aerosol particle with a subcooled liquid droplet and immersion freezing, where particles are already present in a liquid droplet and served as ice nuclei.

Particle composition does not only affect their ability to serve as cloud condensation or ice nuclei but also determines the phase of an aerosol particle. For particles composed of inorganic salts the water content determines whether they are crystalline or liquid. Particles primarily composed of organic matter were traditionally assumed to be liquid under ambient tropospheric conditions. However, in recent years it became increasingly clear that organic particles in the atmosphere might be present in a semisolid or glassy state (Virtanen et al., 2010). The presence of a glassy state (compared to a liquid particle) has significant consequences with respect to water uptake kinetics and diffusivity of oxidants and particle components into the particle bulk and thus might affect composition and particle–cloud interactions (Koop et al., 2011). Particle-phase reactions (i.e., aging) leading to high-molecular weight compounds are a key factor that increases the particle viscosity.

Optical Properties

Particles are indirectly affecting the radiative balance of the atmosphere via cloud formation. In addition, particles are also directly scattering and/or absorbing light. These processes, depending on the particle size, shape, and composition, lead

to a direct cooling (scattering) or warming (absorption) of the atmosphere.

Chemical Composition and Reactivity

Besides physical properties, information about the chemical particle composition is critical to assess comprehensively aerosol effects in the atmosphere. Composition is closely linked to cloud condensation or ice nucleation activities of particles and their optical properties. In addition, only a detailed knowledge of the chemical composition allows establishing the quantitative contribution of the various particle sources because physical properties such as size are rarely source-specific. This is especially of concern for air quality issues, because particle health effects are most likely related to particle composition and because only the anthropogenic particles fraction can be easily regulated.

The chemical composition of aerosols particles is highly complex and variable in space and time and several thousand of compounds have been separated with chromatographic or mass spectrometry techniques (Hamilton et al., 2004). Inorganic salts, minerals, and organic compounds are the major fractions in tropospheric particles. The detailed composition depends, e.g., on the relative influence of anthropogenic vs natural particle sources. In addition the particle composition constantly changes during the entire atmospheric lifetime of the particle due to chemical and physical processes. With increasing atmospheric age condensation of inorganic salts (like nitrate, ammonium, and sulfate) and organics will gradually lead to a more uniform chemical composition of particle composition and relevant physical properties such as hygroscopicity compared to freshly emitted particles.

Major inorganic components are ammonium nitrate and ammonium sulfate, which are often of anthropogenic origin and are therefore dominant particle components over continental regions where they account for roughly 50% (Jimenez et al., 2009) of the total mass for particles below 2.5 μm diameter, as illustrated in **Figure 5**. In contrast, in the marine atmosphere sea-salt components NaCl, KCl, CaSO_4 , and Na_2SO_4 are dominant. Sea-salt particles also contain a large number of organic compounds, which are present at the ocean surface layer and which are the most abundant in the smallest, submicrometer particle fraction of primary marine particles.

Metals have natural as well as anthropogenic sources. Natural sources include mineral dust emitted from (semi-) arid regions in large quantities. These particles are mainly composed of oxides and carbonates of Si, Al, Ca, Fe. The composition and mineralogy of mineral dust bears a close resemblance to the average crustal composition and may be used to identify its source region. Metals from anthropogenic activities are related to industrial processes or traffic sources but account for only a small fraction of the total particle mass.

Water is an abundant but also a highly variable component in atmospheric aerosol particle (see discussion above about hygroscopicity and cloud condensation nuclei). Thus in most studies on particle composition, water is not considered. When particle mass concentrations are reported, e.g., for air monitoring purposes, the particle weight is determined at 50% relative humidity.

Figure 4 Chemical composition of ice nuclei as observed in field experiments. Mineral dust particles and primary biological particles such as bacteria or pollen and spores are the most abundant categories of ice nuclei. Pratt, K.A., et al., 2009. In situ detection of biological particles in cloud ice-crystals. *Nature Geoscience* 2, 398–401.

Figure 5 Typical chemical composition of continental urban aerosol particle (PM_{2.5}).

Carbonaceous Aerosols

The carbonaceous particle mass can be divided into an organic and an inorganic carbon fraction (inorganic minerals containing carbonates are not considered here). Separating the two fractions is important because the inorganic, graphite-like carbon mass is the main light absorbing fraction in tropospheric particles and thus a reliable quantification is crucial to assess radiative properties of the particles. However, the quantitative determination of the inorganic carbon mass is challenging mainly because of the difficulty to separate it efficiently from all organic material. There are a number of analytical methods used to quantify the two fractions using combustion methods followed by a quantification of CO₂ (or CH₄ after an additional reduction step) or using optical methods measuring the total adsorption at different wavelengths (Schmid et al., 2001). In an alternative method (single particle soot photometer) the particles are vaporized in an intense laser beam and the emitted incandescent light over a broad wavelength range is measured. The incandescence is empirically related to particle composition and mass (Slowik et al., 2007). Depending on the method a number of terms such as black carbon, elemental carbon, or soot are used in the literature.

Besides inorganic carbonaceous particle components, organic compounds are a major but very poorly understood fraction of tropospheric particles. The large complexity and variability of the organic particle composition, both spatially and temporarily and the usually low amount of sample available for analysis are the main reasons which limit the use of many analytical techniques. Not only the large number of organic compounds is a challenge for most chemical analytical techniques with several thousand compounds that have been separated and categorized, but also their large range of physical properties such as molecular weight distribution, volatility, polarity, or functional group distribution. Studies attempting to characterize the organic aerosol fraction on a molecular level are often able to identify only 10–30% of the total organic mass (Decesari et al., 2006). Thus, the chemical nature of the vast majority of organic compounds is only very poorly understood

and therefore it is also difficult to clearly identify the main sources of the organic particle fraction.

Nonoxidized hydrocarbons (such as alkanes and polyaromatic hydrocarbons) or only slightly oxidized compounds (e.g., fatty acids) are emitted by primary particle sources. The largest fraction of organics, however, are oxidized compounds and have variety of oxygen functional groups such as carboxylic acids, ketones, alcohols, esters, or peroxides with often multiple functional groups such as polycarboxylic acids. Besides compounds with oxygen-containing functional groups, there is also a large range of nitrogen- and sulfur-containing compounds found in organic particles. The presence of such compounds is more prominent at locations with higher anthropogenic influence (i.e., in polluted air) indicating that SO₂ and NO_x are gaseous precursors of these compounds.

Secondary Organic Aerosol

A majority of these oxidized compounds are not directly emitted but are formed in the atmosphere, either in the gas phase followed by condensation or in the particles by oxidation or condensation reactions. The organic aerosol mass formed through these processes is defined as secondary organic aerosol (SOA) mass.

There are a number of volatile organic compound classes that are efficiently forming SOA, such as aromatics (mainly emitted into the atmosphere due to fossil fuel consumption) and terpenes or sesquiterpenes (biogenic precursors of SOA). The atmospheric oxidation of these SOA-precursor compounds leads to the formation of hundreds of organic oxidation products, some of which are highly oxidized and have a low vapor pressure. The particle formation potential of an SOA precursor depends on their chemical structure and on oxidant concentrations. Especially under intense sunlight and high oxidant conditions SOA can be the dominant fraction of the total organic particle mass. Due to the highly complex mixture present in SOA, it is challenging to describe SOA formation on a fundamental level. The partitioning of an individual organic compound between the gas and the particle phase can be described by its gas–particle partitioning coefficient, K_p , which

mainly depends on the compound's vapor pressure and its activity coefficient in the particle phase as described in eqn [4],

$$K_i = \frac{760 RT f_{om}}{MW_{om} 10^6 \alpha_i p_{L,i}^0} \quad [4]$$

where R is the ideal gas constant, T temperature, f_{om} the fraction of the total particle mass into which the organic components can partition into, MW_{om} the mean molecular weight of the absorbing organic particle mass, α_i the activity coefficient of the compound in the organic particle matrix and $p_{L,i}^0$ the (subcooled) liquid vapor pressure of the compound (Pankow, 1994).

The organic mass formed from an individual compound (aerosol yield, Y_i), or a number of compounds, can be described by eqn [5], where M_0 is total organic mass, K is the gas/particle partitioning coefficient and α is the molar yield of compound i .

$$Y_i = M_0 \sum_i \left(\frac{\alpha_i K_i}{1 + K_i M_0} \right) \quad [5]$$

Because the vapor pressure and activity coefficient of many organic aerosol components are not known which are needed to calculate K_i (see eqn [4]) and because the structure of the vast majority of all particle components is unknown it is not possible to describe SOA formation using these fundamental relationship. However, the particle yield of an individual SOA-precursor gas can be parameterized using the SOA yield equation (eqn [5]). It has been shown experimentally that for most SOA precursors it is sufficient to assume only two particle-phase reaction products with different reaction yield and vapor pressure for a quantitative SOA yield description rather than accounting for the hundreds of compounds actually present in the particle (Odum et al., 1996). This simple model further assumes a linear combination of SOA yield when different SOA precursors are present in the atmosphere. Recently it has been recognized that this simple assumption might not be valid under all conditions.

In addition, in recent years it became clear that model estimates using this approach severely underestimate the (secondary) organic aerosol mass observed in the ambient atmosphere (Volkammer et al., 2006). Potential reasons for this discrepancy are unknown organic SOA precursors or particle-phase reactions that change the chemical mass, composition, or lifetime of SOA in the atmosphere. Particle-phase reactions such as oligomer formation and continuous oxidation are decreasing the volatility of particle components and thus enhancing the particle stability in the atmosphere (Kalberer et al., 2004). Such processes further highlight that SOA particle composition cannot simply be described with compounds formed in the gas phase, which condense into the particle phase but that particle-phase reactions are continuously changing the composition of SOA during the entire atmospheric lifetime of the particle.

Tracers for Aerosol Sources

Despite the difficulties to characterize the particle composition on a molecular level, there have been many attempts to identify

tracer molecules or elements for specific particle sources. A quantitative understanding of source-specific tracers directly at the particle source allows determining the contribution of such a source in the complex ambient particle mixture.

Metals have been frequently used as tracers in source apportionment studies because they do not react in the atmosphere or evaporate as it might be the case with organic compounds. However, metal profiles may overlap between particle sources and thus source profiles are rarely unambiguous for a single particle source. In recent years, metal source profiles combined with organic tracers are being increasingly used to obtain more source-specific tracer profiles (Pant and Harrison, 2012).

A large range of organic tracers has been proposed for a variety of mainly primary sources. One of the most used organic tracers is levoglucosan, which is a tracer for biomass burning particles together with long-chain alkanes, hopanes, and PAHs (Simoneit, 2002). Patterns of PAHs and hopanes, together with steranes and elemental carbon, were used to derive specific emission profiles of diesel and gasoline vehicle exhaust. Other sources identified with organic markers include primary particles from vegetation, food cooking, road dust, and industrial processes (Schauer et al., 1996). The major drawback of organic tracers is their potential reactivity in the atmosphere mainly with OH or NO₃ radicals and a careful characterization of the atmospheric chemistry of potential organic tracers is needed to estimate their suitability.

An alternative technique to identify carbonaceous particle sources and quantify the fraction originating from fossil fuel sources is radiocarbon (¹⁴C) analyses. Because ¹⁴C has a half-life of about 5730 years all ¹⁴C decayed in fossil fuel and thus the identification of ¹⁴C levels in atmospheric aerosols allows for an unambiguous quantification of the carbonaceous particle fraction, which originates from fossil fuel sources. The remaining carbon particle fraction is a mixture of natural and anthropogenic sources, including natural biological particles and biomass burning. Using the ¹⁴C technique it has been shown that elemental carbon is generated mainly from fossil sources. However, in rural areas or developing countries, where wood burning is the dominant source for domestic heating and cooking, 50–70% of the black carbon originates from biomass burning (Gustafsson et al., 2009). Such quantitative information about particle sources is crucial to develop future mitigation strategies to decrease the effect of particles on climate and health.

Heterogeneous Reactions

As mentioned above the chemical composition of aerosol particles changes continuously during their atmospheric lifetime and can significantly influence their effects on climate and health. Chemical reactions of a gas phase compound occurring at the surface or in the bulk of particles are defined as heterogeneous reactions. These reactions can take place in aqueous cloud droplets, in liquid organic particles, or on solid particle surfaces.

Heterogeneous chemical reactions in the atmosphere involve a series of physical processes, including diffusion in the gas phase, accommodation (sticking), and evaporation from the surface. In the case of liquids, diffusion and dissolution will

Figure 6 Physical and chemical processes involved in the transfer of molecules from the gas to the liquid particle phase.

occur in the condensed phase. Chemical reaction may also happen at the gas–particle interface or in the condensed phase. All these processes must be treated together to understand the overall rate of removal of a compound from the gas phase, as any one process can act in a rate determining way. These processes, illustrated for a liquid particle, are represented in **Figure 6**.

The rate of a heterogeneous process is usually expressed in terms of the uptake coefficient, γ , which is defined as the fraction of molecules colliding with the surface that are permanently lost from the gas phase (eqn [6]).

$$\gamma = \frac{\text{number of molecules lost from the gas phase per unit time}}{\text{number of molecules colliding with the surface per unit time}} \quad [6]$$

According to the kinetic theory of gases, the rate of collision of a species A at the surface, per unit area, is $[A] \bullet c/4$, where $[A]$ is the concentration (molecules cm^{-3}) of species A and c the mean molecular speed of the gas molecules.

The rate of removal of molecules at the surface can therefore be expressed as a first-order process with rate (eqn [7])

$$-\frac{d[A]}{dt} = k_{\text{het}}[A] \quad [7]$$

with k_{het} defined as (eqn [8])

$$k_{\text{het}} = \gamma \frac{c}{4} S [\text{cm}^3 \text{ s}^{-1}] \quad [8]$$

where S is the surface area of the atmospheric particles. As well as providing data on the rate of removal of trace gases by aerosol particles, uptake coefficient measurements can be used to deduce mechanistic aspects of the heterogeneous processes.

A useful approach for dealing with general problems of gas uptake rates into clouds and aerosols is the resistance model. This is a simplified representation based on an electrical circuit analogue as shown schematically in **Figure 7**. Each process is expressed as a resistance term and thus can be combined in series or in parallel to obtain the overall rate of the heterogeneous process.

Resistances are expressed as the inverse of the dimensionless uptake coefficients. The resistances $1/\gamma_g$ and $1/\alpha$ represent the

Figure 7 The resistance model describing gas uptake into the condensed phase.

resistance due to gas transport and surface accommodation, respectively, and γ_{sol} and γ_{rxn} describe liquid solubility and reaction, respectively. On the basis of the model illustrated in **Figure 7**, the overall uptake coefficient is expressed as (eqn [9]):

$$\frac{1}{\gamma} = \frac{1}{\gamma_g} + \frac{1}{\alpha} + \frac{1}{(\gamma_{\text{sol}} + \gamma_{\text{rxn}})} \quad [9]$$

where γ is the experimentally determined overall net gas uptake coefficient.

An example for a heterogeneous reaction limited by accommodation is the hydrolysis of nitrogen pentoxide N_2O_5 leading to the formation of nitric acid, a major removal process of nitrogen oxides in the atmosphere. In contrast, the oxidation

of SO_2 to H_2SO_4 by ozone and hydrogen peroxide in cloud droplets is so fast that the overall reaction is controlled by diffusion of SO_2 in the gas phase to the cloud droplet surface. A large number of other heterogeneous atmospheric reactions have been investigated (Crowley et al., 2010).

In recent years, models describing the kinetics of heterogeneous reactions in more detail have been developed, which offer a generalized framework that allows for detailed process description of gas phase, surface and particle bulk physical transport processes and reactions (Pöschl et al., 2007). In addition, models have been developed to specifically describe in detail aqueous phase chemical reactions in cloud droplets to estimate aqueous phase reactions such as N_2O_5 hydrolysis, carboxylic acid formation, or halogen chemistry (Herrmann et al., 2005).

Synopsis

Herein, we discuss the significance and measurement of stratospheric aerosols. Stratospheric aerosols play an important role in the chemistry and radiative influence of the middle atmosphere. In the past several decades, their levels have been highly variable and primarily controlled by a series of low latitude eruptions. Large events, such as the 1991 Pinatubo eruption, reflect incoming solar radiation back into space with a net cooling of the entire Earth though the impact on sensible weather is highly variable across the Earth. Stratospheric aerosols also play a significant role in ozone chemistry.

Introduction

The most basic definition of an aerosol is particles (liquid or solid) suspended in a gas. Generally, when referring to properties of the stratospheric aerosol, it is common to neglect the gaseous media (the atmosphere) and focus only on the particulate material. Unlike the troposphere, where aerosol composition can be highly diverse, in the stratosphere that vast bulk of aerosol is composed of sulfuric acid and water mixtures. The proportion between these two components is dependent on the ambient temperature and available water vapor and most aerosol particles are between 50 and 85% sulfuric acid by mass. In addition to the sulfate–water mixture, many stratospheric aerosols have a nonvolatile core consisting of a wide variety of compositions including meteoric dust, soot, and other materials.

During the past 40 years, stratospheric aerosol levels have been primarily controlled by a series of low latitude (tropical) eruptions which increased aerosol levels by factors as large as 1000 at some locations and required many years to relax to preeruption levels. The relevance of volcanic stratospheric aerosol to climate was graphically demonstrated in the early nineteenth century by weather effects associated with 10 April 1815 eruption of Tambora in Indonesia. The eruption measured 7 on the volcanic explosivity index and is possibly the largest volcanic event of the current era. The eruption injected large amounts of aerosol and aerosol precursors into the stratosphere, which subsequently were dispersed throughout the global stratosphere. This aerosol reflected a portion fraction of the incoming solar radiation back into space with a net cooling of the entire Earth. However, this cooling was not uniformly distributed across the planet but instead influenced weather patterns such that some regions experienced substantial cooling effects while other regions experienced no impact or even warmer than normal weather. Famously, this event produced the well-known ‘Year without a Summer’ in eastern North America where snow fell in New England (United States) in June 1816 and temperatures as low as 4 °C (40 °F) were reported in July as far south as Richmond in the southern United States. Similarly, weather in Europe remained cold and damp throughout the Summer of 1816. Throughout North America and Europe widespread crop failures and poor harvests ultimately lead to increased food prices

and widespread hunger. Given the demonstrated efficient cooling produced by major volcanic eruptions, some scientists have proposed that directly injecting sulfate aerosol or its precursors into the stratosphere (i.e., Geoengineering) could counterbalance global warming.

In addition to these episodic large events, stratospheric aerosol plays a significant role in stratospheric chemistry by providing the surface for a class of processes known as heterogeneous chemical reactions. These reactions play a critical role in ozone chemistry and, as a result, the total surface area density (SAD) provided by stratospheric aerosol is a crucial parameter in understanding changes to ozone. In addition, aerosol even at the lowest levels observed in the measurement record play a subtle role in the radiative balance of climate and may modulate the efficacy of the transport of material from the troposphere into the stratosphere. Some of these materials, such as water vapor, are active greenhouse gases and thus changes to stratospheric aerosol may play an indirect role in modulating climate. While there is debatable evidence for a direct human influence on stratospheric aerosol levels, recent studies on the impact of smaller volcanic events demonstrates that even modest changes have an impact on climate. As a result the need for monitoring the stratospheric aerosol for evidence of human-induced change remains critical.

Measurements of Stratospheric Aerosol

Unlike measurements of stratospheric gas components of the stratosphere, measurements of stratospheric aerosol are not straightforward concentration or mixing ratio measurements. In order to produce a complete depiction of stratospheric aerosol a number of parameters must be measured, inferred indirectly or assumed including composition, size distribution, and the presence of a solid nucleus (and its composition). Most stratospheric aerosol measurements provide limited optical parameters that result from the detailed character of the particle which remains masked to some extent. Ultimately, it is difficult to separate what we know about aerosol from how it is measured.

In general, measurements of stratospheric aerosol can be categorized into two categories: *in situ* and remotely measured. Compared to remote sensing measurements, *in situ*

(‘in position’) measurements are much closer to measuring fundamental aerosol properties. While, by the nature of the measurements, *in situ* datasets do not have the spatial-temporal scope that space-based measurements have, they nonetheless provide crucial validation to the direct optical measurements made from space. They provide estimates of crucial aerosol bulk properties which are far less model dependent than space-based measurements. Space-based measurements provide global coverage on scales of 1-day to 1-month depending on the measurement strategy employed. However, they are limited to bulk optical measurements from which other properties must be inferred. These measurements have limited information content with regard to the details of aerosol properties and thus are dependent on making reasonable assumptions regarding both composition and size distribution. Both approaches are necessary given the strengths and limitations that both exhibit.

***In Situ* Measurements of Aerosol**

The *in situ* measurement of stratospheric aerosol has been conducted using a variety of optical particle counters (OPC). OPCs produce a size distribution by segregating particles into bins based on measuring light scattered from individual particles at a given scattering angle and/or wavelength where amount of light scattered is related to the particle size. The number of bins and the robustness of the corresponding aerosol size distributions is roughly correlated with the platform from which they are deployed. Beyond OPCs, *in situ* stratospheric aerosol measurements have been made employing diverse strategies including particle impactors, quartz crystal microbalances, and backscatter sonde.

Balloon-based optical particles such as the long-lived series operated through the University of Wyoming counters have a nearly 40-year history and important climatological information. These OPCs provide profiles of stratospheric aerosol to as high as 30 km and do not necessarily require recovery of the instrument after flight but provide only a relatively coarse size distribution. The earliest measurements often had only three size bins (0.01, 0.15, and 0.25 μm) and as such inferring bulk aerosol properties like mass or SAD was highly dependent on assumptions regarding the underlying size distribution. Later instruments have more size bins but generally do not fully explore the smaller particle ranges ($<0.1 \mu\text{m}$) and remain dependent on assumptions regarding aerosol size distributions to infer particle’s other properties. Nonetheless, these measurements have the longest consistent measurement dataset and represent a crucial part of the stratospheric measurement ensemble. Some OPCs include modes where the volatile portion of the aerosol is removed and the presence of nonvolatile, presumably solid, components are detected without direct inference of composition.

Airborne OPC instruments can be larger and more complex instruments and are sustainable for multiple flight opportunities. As a result they are able to provide far more detailed size distribution measurements than their balloon-borne cousins. Some of these instruments have extensive field campaign datasets including those associated with the focus cavity aerosol spectrometer (FCAS), the forward scattering spectrometer probe, and the multiangle aerosol spectrometer

probe. Employing a different strategy, the Civil Aircraft for the regular investigation of the atmosphere based on an instrument container OPC flies aboard commercial Lufthansa flights and has produced an extensive set of detailed aerosol and gas species measurements in the upper troposphere and lower stratosphere (UTLS). The inference of aerosol properties from measurements like the FCAS is clear-cut where the measured detailed size distribution can be combined with an appropriate kernel (for SAD, extinction at a given wavelength, etc.) to produce measurements of bulk properties of aerosol without controlling assumptions regarding the form of the underlying aerosol size distribution. However, the composition of aerosol in the upper troposphere must be assumed and is far more complex than in the stratosphere where assuming sulfate aerosol is reasonable under most conditions. Comparisons of aerosol extinction measured by space-based instruments and those from the aircraft-based OPCs generally show an excellent level of agreement. Since all OPCs pump air through their instrument (some accelerating aerosol to aircraft velocities), care must be made to minimize kinetic heating effects and account for the portion which cannot be completely mitigated. This is generally well understood and, where comparisons can be made, it appears that most *in situ* sensors account for these effects well.

The most complete understanding of the composition of aerosol comes from a laser ionization mass spectrometer like the particle analysis by laser mass spectrometry. Data from this instrument confirm the generally accepted inference that stratospheric aerosol at least in the lower stratosphere is primarily sulfate aerosol but also indicates that the presence of organics in the upper troposphere/lower stratosphere is far more common than generally considered by the remote sensing community and that a substantial fraction of stratospheric aerosol contain meteoritic material most likely transported from above 75 km where micrometeorites vaporize and recondense as less than 20-nm-sized particles that either serve as nuclei for stratospheric aerosol or are at least eventually incorporated in the existing aerosol.

Remote Sensing of Stratospheric Aerosol

Space-based measurements form the vast bulk of the global depiction of stratospheric aerosol over the past 4 decades. The data from these instruments provide extensive spatial and temporal coverage not possible from ground or airborne systems. The vertical resolution of these datasets is quite variable from instrument to instrument but in most cases (with the possible exception of the UTLS) adequate for most applications with resolution running from 0.5 to 2.5 km. The most extensive dataset employ the solar occultation technique. In this approach the Sun is observed during each crossing of the terminator (spacecraft sunrise and sunset) and the line-of-sight transmission is measured as a function of altitude. **Figure 1** shows an image demonstrating this measurement geometry. By measuring this at several wavelengths, vertical profiles of gas species like ozone and water vapor along with aerosol extinction coefficient profiles at several wavelengths can be derived. The advantages of this approach are that the Sun is a bright target enabling a small field of view which leads to high vertical resolution. In addition, the geometry is also conducive to high

Figure 1 This photograph from NASA Space Shuttle Atlantis (Mission STS-45) shows sunrise over New Mexico during March 1992. The illuminated layer above the Sun is primarily due to the enhanced aerosol layer from the June 1991 Mt. Pinatubo eruption and vividly demonstrates the signal used by limb-scatter instruments like SCIAMACHY and OSIRIS to infer stratospheric aerosol extinction coefficient profiles. Typically, photographs of sunrise or sunset from the shuttle require substantial filtering to avoid saturation. In this photograph, the Sun is not filtered demonstrating the impact on line-of-sight atmospheric transmission that forms the basis of the solar occultation technique.

quality aerosol measurements as the long path lengths through the atmosphere lead to measurable aerosol values over a wide range of aerosol levels while the stratosphere is also reasonably homogeneous on these horizontal scales in most circumstances. On the other hand, data rates are slow with only ~ 30 profiles per day from most orbits and a full coverage of latitude can take 20–40 days for midinclination orbits while measurements are only made at high latitudes for instruments in sun-synchronous orbits (which are the preferred orbit for most nadir-viewing instruments).

There is a long history of solar occultation instruments with the foremost being the Stratospheric Aerosol and Gas Experiment (SAGE) series, which includes the Stratospheric Aerosol Measurement (SAM II, 1978–93), SAGE (1979–81), SAGE II (1984–05), and SAGE III/Meteor 3M (2002–05). These made aerosol extinction coefficient measurements at 1–9 wavelengths from 385 to 1545 nm with all having a channel near 1000 nm where aerosol is a dominant component (relative to molecular scatter and gas absorption) for even the lowest aerosol levels observed in the stratosphere over the past 30 years. On the down side, while these measurements have been used successfully to infer many aspects of aerosol and stratospheric morphology, the visible/near infrared measurements by these measurements have limited information about the underlying composition and size distribution of the aerosol

in the stratosphere. The wavelength dependence primarily provides information about the largest aerosol present but is insensitive to the smallest aerosol present particularly those with radii below 100 nm. As a result, inferences of size distributions and crucial aerosol bulk properties like SAD are particularly model dependent (most often assuming a single mode log-normal size distribution) and can have substantial uncertainties and may tend to underestimate SAD at low aerosol levels (depending on the model used). Other solar occultation instruments include the Polar Ozone and Aerosol Measurement (POAM) series. Like SAM II, these instruments were in sun-synchronous orbits and made valuable polar vortex measurements of ozone and aerosol during their missions (POAM II, 1993–1996; POAM III, 1998–2005).

The Halogen Occultation Experiment (1991–2005) was also a solar occultation instrument but operated in the thermal infrared where it measured ozone and other gas species. It also inferred aerosol extinction coefficient at four wavelengths. The information content of these aerosol measurements is quite different from the visible/near infrared measurements made by the SAGE and POAM series as sulfate aerosol is an absorber beyond a wavelength of about $2.8 \mu\text{m}$ as opposed to a scatterer at shorter wavelengths. This difference fundamentally modifies the information content of these measurements such that while infrared aerosol measurements have little information about

aerosol size they are almost directly proportional to total aerosol volume including even the smallest aerosol present. While this limits the information content of these measurements by themselves, it is clear that the combination of visible/near infrared and thermal infrared aerosol extinction coefficient measurements substantially reduces the uncertainties in the inference of aerosol bulk properties such as SAD and this combined approach is a necessary step in improving the utility of space-based aerosol measurements. Following the 1991 eruption of Mt. Pinatubo, the space shuttle-based Atmospheric Trace Molecule Spectroscopy Experiment instrument was able to resolve features caused by sulfate aerosol absorption in the infrared in a manner analogous to the measurement of gas species. This is typically not possible except when aerosol levels are substantially enhanced. An additional source of thermal infrared measurements of stratospheric aerosol employs the limb emission technique. In this approach, the emission of the atmosphere is observed in the limb direction and the wavelength dependence of this emission is primarily used to infer profiles of gas species. In this case, aerosol extinction coefficient can be inferred as a slowly varying component in regions of the infrared spectra where the atmosphere is not strongly emitting/absorbing. This is most easy to accomplish during enhanced periods as was demonstrated by cryogenic limb array etalon spectrometer, which operated during the peak of the post-Pinatubo eruption period (1991–93). During lower level aerosol periods, this measurement is more challenging though Michelson Interferometer for Passive Atmospheric Sounding (MIPAS) has demonstrated some ability to infer aerosol extinction profiles.

Some additional solar occultation measurements that continue past the 2005 aerosol instrument Armageddon include aerosol measurements by the Atmospheric Chemistry Experiment instruments Fourier transform spectrometer Sun imager and the Measurement of Aerosol Extinction in the Stratosphere and Troposphere Retrieved by Occultation remain in the developmental stage but may eventually continue the solar occultation aerosol measurement ensemble.

Since the demise of the SAGE series of instruments in 2005, the stratospheric aerosol record has become dependent on instrument using a variety of techniques which provide their own strengths and weaknesses. The most similar to solar occultation is the global ozone monitoring by occultation by stars (2002–12), which employed stellar occultation to measure ozone and aerosol extinction at visible wavelengths. The instrument was capable of performing occultations using a number of stars during the night portion of each orbit and thus produced profile data at a significantly higher rate than are possible for solar occultation. On the other hand, the relatively dimmer target and the effects of stellar scintillation (twinkling) complicate the data analysis such that aerosol data below 20 km are difficult and substantial care must be made while using these data. Currently, data from this instrument are only available at a single wavelength but are undergoing a major revision that may dramatically improve the utility of this instrument's aerosol data in the future.

The most likely heirs to the solar occultation heritage of stratospheric aerosol measurements are limb scatter and space-based lidar. In the past decade, three limb-scatter instruments have provided measurements of ozone and other gas

species: Odin spectrometer and infrared imager system (OSIRIS, 2002–present), scanning imaging absorption spectrometer for atmospheric chartography (SCIAMACHY, 2002–12), and ozone mapping and profiler suite (OMPS, 2011–present). More recently, there has been a concerted effort to similarly derived aerosol extinction coefficient profile information from these data. This was initially done simply to account for the impact of aerosol on scattering of solar radiation in the stratosphere in the derivation mission critical products such as ozone. However, the presence of a clear aerosol dependence on the measurements makes an aerosol measurement possible. Limb-scatter aerosol produces complete global coverage in a single day compared to approximately a month for solar occultation. **Figure 1** shows an image demonstrating this measurement geometry.

The limb-scatter instruments observe the limb of the Earth's atmosphere (away from the Sun) and measure the sunlight scattered by the atmosphere into the instrument. The amount of light is dependent on absorption along the path by gas species, scattering out of the line of sight by molecules and aerosol and scattering into the field of view of the instrument by molecules and aerosol. The angle between the position of the Sun, a point in the atmosphere, and the instrument influences the amount of light scattered into the instrument. While this scattering efficiency is well known for molecular scatter, the scattering by stratospheric aerosol is dependent on the size distribution. In the past, the aerosol phase function was inferred from other data and provided to the instrument analysis as a priori data. However, more recent work to use the observed wavelength dependence to infer the aerosol scattering function holds substantial promise to remove the dependence on this external information. Limb-scatter measurements are made over as similar domain as solar occultation information and have the same lack of information on the details of the underlying size distribution. The inference of an effective size distribution (one that reproduces the observed measurements) appears to be adequate to enable good quality aerosol extinction coefficient measurements though concomitant inferences of aerosol bulk properties have the same limitations as those from solar occultation. As a result the next generation of aerosol datasets from these instruments should be substantially improved over earlier versions and are applicable to science applications. However, it will be important to demonstrate that data quality is independent of scattering angle and overlap between limb instruments and solar occultation data in 2002 and 2005 and beginning again in 2014 with the launch of SAGE III/ISS will provide important calibration between these datasets that is crucial to maintaining a trendable aerosol extinction climatology dataset.

The use of laser ranging and detection (lidar) to measure stratospheric aerosol from space is unique compared to any other approach in that it is an active measurement as opposed to a passive measurement (using ambient sources of radiation like the Sun or atmospheric thermal emission). There is a substantial history of ground-based lidar measurements of the stratospheric aerosol dating back as far as the 1960s. Despite the limited spatial coverage they are an important resource in understanding the long-term variability of stratospheric aerosol. More recently, space-based lidar has used a laser to probe the atmosphere and produce high

vertical resolution profiles of aerosol backscatter coefficient. Nominally, space-based lidar can continually produce stratospheric aerosol analyses throughout an orbit as was demonstrated by the first space-borne lidar, Lidar In-space Technology Experiment in September 1994. In practice, the signal is generally small from the stratosphere and with the additional noise associated with daytime measurements; only data from the dark half of the orbit can be used to depict the stratosphere and thus is somewhat analogous to limb-scatter measurements.

The Cloud-Aerosol Lidar with Orthogonal Polarization (CALIOP) has produced lidar data since 2006. This has been a relatively low aerosol-loading period in the stratosphere and substantial averaging of the individual profiles is required to produce a meaningful stratospheric product. In addition, given the low aerosol levels, the calibration of the instrument is a crucial element of a stratospheric product. Typically, lidar is calibrated using a level in the atmosphere that is very low in aerosol treated as aerosol free. In the case of CALIOP, altitudes between 36 and 39 km are used for calibration though the aerosol is most likely on the order of a few percent (1–2%) of the molecular value. Since stratospheric backscatter levels are only on the order of 5–20% enhanced relative to molecular value, the potential for bias in the measurements remains. Nonetheless, CALIOP has been very useful in observing stratospheric aerosol and polar stratospheric clouds (which occur in polar winter). CALIOP has observed a number of volcanic plumes in the UTLS regions as well as aerosol enhancements in the upper troposphere associated with the Asian monsoon convection. Ground-based observations from fixed locations had inferred a stratospheric aerosol trend above 20 km which had been attributed to Chinese sulfur emissions but, as CALIOP data demonstrated, was actually the result of small volcanic events and their transport within the broad stratospheric circulation. While these measurements are challenging, they clearly bring an exciting new capacity to the monitoring of stratospheric aerosol.

The Lifecycle of Stratospheric Aerosol

In many ways, the processes controlling stratospheric aerosol levels, their distribution within the stratosphere, and how they exit the stratosphere can be divided into two categories: periods following significant volcanic injections of aerosol and its major precursor SO_2 in the tropics; and periods well away from these events, where the source of aerosol is more complex and generally less well understood. Figure 2 shows a schematic of the stratospheric aerosol lifecycle. Since the advent of global measures in 1979 the former category can be assigned to a highly volcanic period stretching between the 1982 eruption of El Chichón (Mexico) and the end of the recovery of the 1991 Mt. Pinatubo eruption in the late 1990s. The less volcanic, though not free of volcanic effects on the stratosphere, can be assigned to the period before 1982 and more extensively to the period following 2000 up to the present. Episodic and rare extreme fire events can also occasionally reach the stratosphere as was observed after the mass Black Saturday fire in Australia in February 2009.

During the volcanic period, the global stratospheric aerosol processes were controlled by five or six eruptions. In addition to Pinatubo and El Chichón, they are Nevado del Ruiz (1985, Colombia), Nyamuragira (1986, Democratic Republic of the Congo), Kelut (1990, Indonesia), and Cerro Hudson (1991, Argentina). The 1991 Cerro Hudson eruption is the only event occurring outside of low latitudes and occurred shortly after the Pinatubo eruption which had the largest stratospheric impact of any eruption in the twentieth century. As a result, it was only distinctly discernible in the measurement dataset for a few months before being masked by the massive Pinatubo event. The low latitude events can have the most long-lasting influence on stratospheric aerosol levels depending on the altitude to which the volcanically injected SO_2 is injected. This injection is observed by a number instrument such as the total ozone mapping spectrometer and similar nadir-viewing ultraviolet spectrometers since SO_2 has an absorption feature in the

Figure 2 A figure showing the lifecycle of stratospheric aerosol and the primary processes controlling it. From SPARC (2006).

ultraviolet bands where ozone is measured. Aura/MLS has demonstrated a capacity for SO_2 profiling of stratospheric volcanic SO_2 plumes. In the case of Kelut, the impact was mostly felt between the tropopause and 20 km and aerosol from this event was transported from the tropics to higher latitudes within a few months from which it was transported into the troposphere where it is eventually washed out of the atmosphere. On the other hand, the other low latitude events had significant SO_2 injections at altitudes above 20 km into a region of the stratosphere referred to as the 'leaky tropical pipe.' This is a region in which transported to higher latitudes is suppressed and where a volcanic enhancement can be maintained for many years. In the case of Pinatubo, the tropical pipe remained clearly enhanced as late as 1999 or more than 7 years following the eruption. For this reason, the tropical pipe is sometimes colloquially referred to as the tropical aerosol reservoir as it clearly acts as such particularly in the volcanic period. Figure 3 shows the stratospheric optical depth (vertically integrated aerosol extinction coefficient) between 1979 and 2005 and shows the persistence of an enhanced tropical aerosol reservoir following the Pinatubo eruption.

Once the SO_2 is injected it undergoes a photochemical processing that eventually produces gaseous sulfuric acid (H_2SO_4). Since sulfuric acid has a low saturation vapor pressure, it readily condenses onto existing aerosol or nucleates new aerosol using homogeneous (without a condensation nuclei) or using ambient solid particles as nuclei including associated volcanic ash, meteoric dust, and organic particles. Once this aerosol has formed, particle number densities can be much higher than that typically observed in the stratosphere ($\sim 10 \text{ cm}^{-3}$) and the aerosol actively coagulates into a progressively larger aerosol. As a result, it is commonly observed that aerosol size is strongly correlated with bulk aerosol levels (measured by mass or other quantity).

In the immediate aftermath of a major eruption, sedimentation of the largest aerosol can transport significant amounts of aerosol out of the stratosphere and into the upper tropical troposphere where it can be permanently removed from the atmosphere by washout. While the upper tropical troposphere is generally a very low aerosol level region, after the Pinatubo eruption, the level of aerosol in this region increased many fold

primarily as the result of sedimentation. As aerosol levels recover toward preeruption levels, large aerosols are preferentially removed by this process and as aerosol levels decline *in toto*, the particle size also decreases and sedimentation becomes an ineffective mechanism for the removal of aerosol from the stratosphere. Aerosol within the tropical pipe is then removed by two mechanisms: meridional transport to higher latitudes and vertical transport to higher altitudes.

While transport from the tropical pipe is suppressed, it is still a critically important mechanism for the transport of material to higher latitudes. It is generally most efficient into the winter hemisphere at all altitudes but particularly below 20 km. At higher latitudes, the efficacy of this transport is governed by the phase of the quasi-biennial oscillation (QBO) which is a periodic oscillation of the equatorial zonal wind between easterlies and westerlies with a mean period slightly longer than 2 years. In the easterly phase of the QBO, transport out of the tropics is suppressed while in the westerly phase, transport is somewhat more efficient. As a result, the rate at which aerosol is transported to higher latitudes shows a pronounced QBO signal away from tropical latitudes. The efficacy of transport as driven by the phase of the QBO can cause a delay in the arrival of aerosol from even a large event, which can lead to some confusion regarding the source of aerosol observed by ground-based site months or perhaps more than a year after an eruption.

Within the stratosphere, air is generally transported upward in the tropics and then poleward where it is transported downward eventually crossing the tropopause from the stratosphere into the troposphere. This circulation is known as the Brewer–Dobson circulation and this circulation plays a significant role in defining the distribution of aerosol in the stratosphere. The QBO modulates the generally upward Brewer–Dobson vertical transport in the tropical stratosphere. The vertical transport is more efficient during the easterly phase of the QBO and suppressed during the westerly phase. Following a major eruption like Pinatubo, heating of the stratosphere due to the presence of the aerosol can increase vertical transport leading to enhanced aerosol levels to altitudes as high as 35 km. Aerosol is not a passive tracer of vertical transport as sedimentation continues to play a role such that

Figure 3 This figure shows the SAM II/SAGE I/SAGE II 1020-nm stratospheric aerosol optical depth record for 1979–2005 with the times of significant stratospheric injections denoted on the figure. The role of the leaky tropical pipe as a reservoir of aerosol from intense events in the tropics is clearly visible particularly in the period between 1985 and 2000.

aerosol is transported upward more slowly than would be expected by the observed vertical velocities. In addition, since the stratosphere warms with increasing altitude, its capacity to hold gaseous sulfuric acid increases and the sulfate aerosol evaporates more with increasing altitude and the volatile part of the aerosol is essentially completely evaporated by 30–35 km where the ‘top’ of the sulfate aerosol is dependent on the overall aerosol levels. This general morphology is shown in Figure 4. The combination of sedimentation and evaporation gives rise to the observed aerosol layer within the stratosphere. This is often referred to as the ‘Junge layer’ after the scientist who first observed the layer. The gaseous sulfuric acid undergoes photochemical modification and returns to an SO_2 reservoir. This gas rather than material is transported to higher latitudes, where it is transported downward to the lower stratosphere, where it returns first to gaseous sulfuric acid and then recondenses to sulfate aerosol. While the downward transport at high latitudes occurs year-around, it is most effective in the polar winter when diabatic cooling forms the polar vortex (the region in which polar stratospheric clouds form and the ozone hole forms). Since the interior of the polar vortex contains air with very little sulfate aerosol and isolated from aerosol-bearing midlatitude air, the aerosol formation process is often noted near 25 km in wintertime *in situ* aerosol datasets.

Aerosol is removed at high and midlatitudes by a combination of processes. In addition to the downward motions across the tropopause associated with Brewer–Dobson circulation, sedimentation can still be effective once the aerosol is in the vicinity of the tropopause. Bulk stratosphere to troposphere exchange, such as that occurs around tropopause folds, can also remove aerosol. Once in the troposphere, most of the aerosol is scavenged by clouds and precipitation and permanently removed from the atmosphere.

Stratospheric aerosol levels even during the nominally ‘nonvolcanic’ periods are still heavily influenced by small injections of volcanic materials into the tropical UTLS and by direct injection of aerosol into the midlatitude and lowermost polar stratosphere. In the tropics, in addition to periodic volcanic influences, there are also nonvolcanic sources of sulfur-bearing gases which help to define aerosol levels during these relatively low aerosol periods. The most important of these is carbonyl sulfide (OCS) whose source is a combination of natural (primarily oceanic) and human-derived sources. OCS is long-lived in the troposphere and there is significant transport of OCS to the stratosphere across the tropical tropopause. Once in the stratosphere, it primarily remains unchanged until it reaches an altitude of ~ 25 km where it is photolyzed and eventually its sulfur is converted to sulfate aerosol. The lifetime

Figure 4 (a) Monthly mean extinction ratio (525 nm) profile evolution in the tropics (20°N – 20°S) from January 1985 to November 2012 derived from (left) SAGE II extinction in 1985–2005 and (right) CALIOP scattering ratio in 2006–2012, after removing clouds below 18 km based on their wavelength dependence (SAGE II) and depolarization properties (CALIOP) compared to aerosols. Black contours represent the extinction ratio in log-scale from 0.1 to 100. The position of each volcanic eruption occurring during the period is displayed with its first two letters on the horizontal axis, where tropical eruptions are noted in red. The eruptions were Nevado del Ruiz (Ne), Augustine (Au), Chikurachki (Ch), Kliuchevskoi (KI), Kelut (Ke), Pinatubo (Pi), Cerro Hudson (Ce), Spur (Sp), Lascar (La), Rabaul (Ra), Ulawun (UI), Shiveluch (Sh), Ruang (Ru), Reventador (Ra), Manam (Ma), Soufrière Hills (So), Tavurvur (Ta), Chaiten (Ch), Okmok (Ok), Kasatochi (Ka), Fire/Victoria (Vi*), Sarychev (Sa), Merapi (Me), and Nabro (Na). Updated from Figure 1 of Vernier et al. (2011). (b) Mean stratospheric aerosol optical depth in the tropics (20°N – 20°S) between the tropopause and 40 km since 1985 from the Stratospheric Aerosol and Gas Experiment (SAGE II) (black line), the global ozone monitoring by occultation of stars (GOMOS) (red line), and CALIOP (blue line). Updated from Figure 5 of Vernier et al. (2011).

of tropospheric SO₂ (from either human-derived or natural sources) is extremely short primarily due to its solubility in water. However, it is produced in prodigious quantities and some of this material is transported into the stratosphere. Observations by *in situ* sensors suggested that substantial new particle formation occurs in the upper tropical troposphere and so it is possible that much of the SO₂ entering the stratosphere has already been converted into aerosol. While substantial uncertainties surround the amount of SO₂ directly entering the stratosphere, it appears at this time that SO₂ and OCS each account for about half of the flux of sulfur into the stratosphere.

Understanding the transport of sulfur across the tropical tropopause is difficult. This is primarily due to difficulty in measuring SO₂ at background, nonvolcanically enhanced levels at the tropopause. This measurement is currently only possible using airborne instrumentation that strongly limit our knowledge of the sulfur budget in this climate-influential region. This is due to the fact that SO₂ lacks strong spectral features (which are not masked by other absorbing gases) and measurements possible during large volcanic events are not possible for SO₂ levels 1000 times or more smaller. Recent advances by the MIPAS science team show that the basic knowledge of SO₂ morphology is correct. Enhanced SO₂ is observed up to the tropical tropopause above which it declines rapidly as it is apparently converted to aerosol. Between 25 and 30 km it is also enhanced apparently by the conversion of OCS to SO₂ on its way to becoming sulfate aerosol. Above 35 km, it is again enhanced as the evaporation processes leads to the photochemical conversion of sulfuric acid to SO₂. The ability to produce these measurements is a significant achievement. There are a number of other gases that may contribute to the flux of sulfur into the stratosphere. These include dimethyl sulfide and CS₂. While they are unlikely to enter the stratosphere directly in any significant amount, they can be converted into both OCS and SO₂ and contribute to the stratospheric sulfur budget in a small way in those forms.

A variety of organic and inorganic compounds contribute to the overall aerosol loading particularly in the lower tropical stratosphere where they may form a significant fraction of the observed aerosol. Recent *in situ* measurements in the upper troposphere during several field campaigns (TROCCINOX, SCOUT-AMMA, SCOUT-O3) have revealed the presence of newly formed particles at and below the tropopause (350–370 K). In relation to those findings, aerosol composition measurements using mass spectrometers suggest that a large fraction of this aerosol population could be composed of organic materials. This modifies substantially the idea that aerosol near the tropopause and in the lower stratosphere are primarily sulfate. More research is needed to fully understand

the composition and lifetime of those aerosols, which can have a profound impact on the lifetime of thin cirrus clouds in the upper troposphere and climate. In addition, fire products particularly from biomass burning by natural human-directed sources has been shown to contribute to the overall aerosol levels. This has particularly been shown in the CALIOP data following the Victoria (Australia) megafire of 2009 when products of the fire were seen to gradually ascend into the stratosphere to at least 20 km. This has also been observed at high latitudes where boreal fires create pyrocumulonimbus clouds capable of penetrating the lower stratosphere. The long-term significance of these injections is not well known. On the other hand, measurements in the lower stratosphere show that up to half of all aerosols show evidence of the presence of meteoritic material. This material enters the stratosphere from the mesosphere and may be a key nuclei for the formation of sulfate aerosol.

Synopsis

Aerosols are solid or liquid particles either directly emitted into the atmosphere or converted from gaseous precursors. Both natural processes and human activities generate aerosols. They affect visibility, air quality, formation of clouds, and the energy budget of the Earth. Aerosols remain in the troposphere for up to 2 weeks, where they experience chemical transformation and long-range transport.

Introduction

Atmospheric aerosols are solid and liquid particles in suspension in the air, ranging in size from a few nanometers to tens of microns (10^{-9} – 10^{-5} m), with the exception of cloud droplets and ice crystals. Natural sources of aerosols include sea salt generated from breaking waves, mineral dust blown from the surface by wind, and organic aerosols from biogenic emissions. Artificial, also called anthropogenic, aerosols include sulfate, nitrate, and carbonaceous aerosols, and are mainly from fossil fuel combustion sources. The first aerosol studies were motivated by visibility, and in 1880 the British scientist John Aitken correctly postulated that aerosol particles act as nuclei for the condensation of water vapor to form fog and clouds. In the second part of the twentieth century, aerosol particles were linked to an increase in human respiratory diseases and acid rain, prompting the need to improve air quality by reducing emissions of aerosols and their precursors. At the same time, scientists started quantifying the impact of aerosols on the Earth's energy budget and simple aerosol representations were introduced in weather forecast and climate models. Climatologies of aerosols in the troposphere have been developed over time, tailored to the diverse interests in aerosol properties. Climatologies of aerosol surface concentrations and chemical composition originate from air quality monitoring networks such as the European Monitoring and Evaluation Programme and the Clean Air Status and Trends Network of the United States Environmental Protection Agency. Dedicated instrumented aircraft campaigns provide regional snapshots of aerosol composition and size across the lower atmosphere, including information on aerosol microphysical properties and vertical profiles. Networks of remote sensing instruments have been deployed at selected sites worldwide, forming for example the Aerosol Robotic Network (AERONET). AERONET sun photometers provide measurements of the column-integrated extinction of visible or near-infrared radiation by aerosols, called optical depth, and these measurements can be inverted to provide an estimate of aerosol size. The launch of dedicated satellite instruments beginning in the late 1990s provides a global view of aerosol distributions of optical depth. More recently, vertical aerosol distribution has been routinely observed by lidars, located on the ground, aboard aircrafts, or on satellite platforms. In parallel to improved observational capabilities, numerical models have developed and provide daily aerosol forecasts, increasingly often initialized from

assimilation of satellite observations, as well as centennial simulations for climate projections. Numerical models vary in the number of aerosol species they include and in the number of aerosol characteristics they are able to represent depending on the need for computational speed.

In spite of those diverse sources of data, there are a number of difficulties associated with obtaining the aerosol climatology that fits a given application. By definition, aerosols encompass a large range of particle sizes and chemical compositions. Their sources are very diverse and unevenly distributed across the globe. Aerosols are removed from the atmosphere primarily by spatially inhomogeneous precipitation processes and, to a smaller extent, turbulence. Thus, aerosols have a relatively short residence time in the troposphere of typically up to 1 or 2 weeks. Consequently, aerosol concentrations vary greatly in time and space, both horizontally and vertically, in contrast to well-mixed greenhouse gases like carbon dioxide. Well-defined aerosol plumes can often be identified in observations, with aerosol number and mass varying by orders of magnitudes within a few kilometers in the horizontal and a few hundred or even a few tens of meters in the vertical across the plume. Measurements at the surface may therefore not be indicative of aerosol concentrations and properties higher up in the atmosphere. There are also several ways to characterize aerosols. Since aerosols are typically present in large numbers in the atmosphere, their population is described by its size distribution, which gives the number, surface area, or volume of the particles as a function of their radii. As depicted in [Figure 1](#), a typical tropospheric aerosol size distribution exhibits several maxima, called modes. The smaller particles, with radii smaller than 50 nm, belong to the nucleation and Aitken modes and provide most of the total aerosol number. The accumulation mode covers particles with radii up to 0.5 μm , which dominate the aerosol surface area. Both Aitken and accumulation modes are often called fine modes to contrast with the coarse mode, which comprises particles larger than 0.5 μm and makes up the bulk of aerosol volume. Minima in the size distribution arise from coagulation processes, where smaller particles of favorable sizes aggregate into larger particles. Air quality networks routinely report aerosol concentrations for particles with aerodynamic diameters smaller than 2.5 and 10 μm , labeled Particulate Matter (PM) 2.5 and PM10, respectively. Air quality regulations impose thresholds on both the annual average and daily average of PM concentrations in many countries. In Europe, daily average PM10

Figure 1 Distribution of the volume of aerosol particles as a function of their radii, as sampled by the Facility for Airborne Atmospheric Measurements aircraft (black lines) and inverted from ground-based sun-photometer measurements of the Aerosol Robotic Network (gray lines). Panels gather measurements of generic aerosol types at different locations: (a) Industrial aerosol, (b) Mineral dust aerosol, (c) Biomass-burning aerosol, and (d) Marine aerosol. concentrations should not exceed $50 \mu\text{g m}^{-3}$ for more than 35 days per year. In newly industrialized countries, where air quality regulation is weaker, PM10 concentrations routinely exceed $100 \mu\text{g m}^{-3}$ on an annual average.

Aerosols are also characterized by their production processes and chemical composition. Primary aerosols are emitted into the atmosphere directly as particles. They include the carbonaceous by-products of incomplete combustion processes and wind-blown mineral dust aerosols. In contrast, secondary aerosols originate from gas-to-particle conversions. Gaseous precursors, such as sulfur dioxide and ammonia, are oxidized in the dry atmosphere or in clouds and become soluble in water. Eventually, a large fraction of the emitted precursor enters the aerosol phase, dissolved in a droplet. As such, water represents a sizable fraction of the total aerosol mass. Gas-to-particle conversion processes also mean that aerosols are part of the chemistry of the atmosphere and indirectly affect the concentrations of gaseous species such as ozone and methane. Aerosol populations are typically of diverse chemical composition and their mixing state can be both internal, where the mixed composition lies within the same particle, and external, where each particle has a chemically distinct composition. Particle size can be a simplified marker of the production process. Fine-mode aerosols often originate from gas-to-particle conversion or combustion processes. Coarse-mode particles typically originate from mechanical processes such as wind friction. The shape of the particles also depends on the production process: aerosol solutions are spherical droplets. Combustion aerosols, grains

of mineral dust, and pollens have more complex, irregular shapes.

Aerosols can finally be characterized by their natural or anthropogenic origin. This distinction is difficult to obtain from observations alone, but is important for climate studies. Aerosols emitted into the atmosphere by human activities since the start of the industrial revolution have scattered and absorbed additional solar and thermal radiation. They also have modified cloud droplet sizes and number, again affecting solar radiation, albeit indirectly. In effect, anthropogenic aerosols have changed the radiative balance of the Earth in a process called radiative forcing. Although uncertain, this forcing is estimated to be negative, and the climate system responds by cooling. Estimates for the year 2000 suggest that aerosol forcing compensates two-thirds of the positive forcing by long-lived greenhouse gases. Local climate changes driven by anthropogenic emissions can also affect emissions of natural aerosols, desertification being a typical example. In that case, the anthropogenic or natural classification of the aerosol is not obvious.

Sources of Tropospheric Aerosols

In this section, we distinguish four aerosol categories that can be identified in observations, and are represented in numerical models: fine-mode anthropogenic aerosols, mineral dust, marine aerosol, and fine-mode natural aerosols. Emissions of tropospheric aerosols are estimated by national inventories,

Table 1 Approximative present-day range of anthropogenic and natural emission rates of primary aerosols and aerosol precursors. Units are Tg per year, as mass of sulfur for sulfur dioxide and DMS, mass of nitrogen for ammonia, and mass of carbon for VOCs and carbonaceous aerosols

Primary aerosol or precursor	Anthropogenic emission rate	Natural emission rate
Sulfur dioxide (SO ₂)	50–90	10
Ammonia (NH ₃)	20–50	10
VOCs	5–40	80–200
Carbonaceous aerosols from fossil fuels	20–50	
Carbonaceous aerosols from biomass burning	50–90	20–40
Mineral dust aerosols	40–130	1000–3000
Sea-salt aerosols		2000–10 000
DMS		10–60
Biogenic bacteria and pollens		100–1000

VOCs, Volatile organic compounds; DMS, Dimethylsulfide.

derived from satellite observations, or inverted from numerical models with assimilation of satellite observations. Those estimates are uncertain and typically within a factor two to three of each other. [Table 1](#) summarizes the current emissions of aerosol precursors and primary aerosols. For most species, anthropogenic emission rates dominate total emissions. Consequently, anthropogenic aerosols dominate aerosol mass in most industrialized regions. They also contribute largely to aerosol number: polluted cities can exhibit more than 10^5 particles cm^{-3} , compared to 100 cm^{-3} in oceanic background. Aerosols and their precursors are injected into the atmosphere from the surface, with the exception of

chimney-level industrial emissions, forest fires, and volcanic emissions, which are injected at several hundreds of meters because of buoyancy effects or local topography. Gas-to-particle conversions can however happen in the free troposphere, where nucleation of new aerosol particles has been observed. Emission rates only give a partial view of aerosols: their residence time in the atmosphere and other properties relevant to different aerosol impacts are also important. In climate studies, for example, the strength of aerosol interaction with radiation, and the ability of specific aerosol species to form cloud condensation nuclei must be taken into account.

Fine-Mode Anthropogenic Aerosols

[Figure 2](#) shows the distribution of aerosol optical depth attributed to fine-mode anthropogenic aerosols in a numerical model using data assimilation of satellite aerosol retrievals. North America, Europe, and Asia are associated with a sizable increase in optical depth between winter and summer months. Ground measurements show that those regions are associated with primary aerosols and aerosol precursors that are by-products of industrial and agricultural activities, and the combustion of fossil fuels. Industrial aerosols typically reside in the atmosphere for 3–5 days.

Anthropogenic aerosol precursors are sulfur dioxide, ammonia, and volatile organic compounds (VOCs). Sulfur dioxide oxidizes into sulfuric acid and, in most of the troposphere, ammonium sulfate aerosols. This photolytic process is more efficient during the summer months. An emission inventory compiled in 2010, summarized in [Figure 3](#), suggests that 42% of anthropogenic sulfur dioxide emissions come from power plants, 29% from industries,

Figure 2 Seasonal distributions (2003–10) of aerosol optical depth at $0.55 \mu\text{m}$ attributed to fine-mode anthropogenic aerosols in the Monitoring Atmospheric Composition and Climate reanalysis of the European Centre for Medium-Range Weather Forecast forecast model with assimilation of Moderate-resolution Imaging Spectroradiometer total aerosol optical depth retrievals.

Figure 3 Anthropogenic emissions of aerosols and aerosol precursors for the year 2010, according to the datasets developed as part of the Climate Model Intercomparison Project Phase 5. Left column: sector-based charts, in Tg per year. Right column: Distributions of total emissions, in $\text{ng m}^{-2} \text{s}^{-1}$. Emissions of sulfur dioxide, ammonia, and carbonaceous aerosols and volatile organic compounds are given as masses of sulfur, nitrogen, and carbon, respectively.

and 12% from shipping, with the remainder mostly provided by the transport and domestic sectors. Other inventories may provide different sector-based partitions and total emissions. Ammonia and NO_x oxidize into ammonium nitrate aerosols. Ammonia emissions are estimated at 78% by the agricultural sector, from livestock and fertilizers (Figure 3). VOCs are precursors of secondary organic aerosols. Anthropogenic VOC emissions originate from the transport, energy, solvents, and domestic sectors. The combustion of fossil fuel and biofuel also emits primary carbonaceous aerosols in the atmosphere. Those aerosols are a mixture of pure soot particles, named black carbon aerosols, and particles made of carbon bound in an organic compound, named organic carbon aerosols. Due to the use of cooking stoves, black carbon aerosols are particularly abundant in India. Fossil fuel carbonaceous emissions come mainly from the domestic, industrial, and transport sectors (Figure 3).

Anthropogenic aerosols in South America, Africa, and Indonesia are different and dominated by particles associated with the incomplete combustion of biomass. The seasonality of those aerosols is driven by the clearance of forested areas and the fertilization of crop fields at the start of the growing season. The biomass-burning aerosol season starts in December in western Africa, then gradually moves southward, ending around September in the Congo basin and southern Africa. In South America and Indonesia, the season tends to start in late August, peaks in September, and ends in October, although there can be significant year-year variability in the timing. Aerosol concentrations close to large fires can be very high, up to 1 mg m^{-3} . Annual emissions of biomass-burning aerosols mainly include primary emissions of black and organic carbon aerosols, with the former representing about 10% of total emissions, but also sizable emissions of aerosol precursors such as ammonia and VOCs

(Figure 3). Biomass-burning emissions partly depend on political aspects and exhibit large interannual variability, especially in South America. According to numerical models, biomass-burning aerosols typically reside in the atmosphere for 6–7 days.

Mineral Dust Aerosols

Mineral aerosols are produced by the friction of near-surface winds onto bare soils, and are mainly coarse-mode particles. When wind speeds exceed a critical threshold, mineral particles are emitted from the surface. Smaller particles remain suspended in the atmosphere, while larger particles impact the surface and release smaller particles into the air in a process known as saltation. In addition to the seasonality of wind regimes, dried and less vegetated soils are more prone to mineral dust production. Preferential sources for mineral dust are low-lying regions of silts and sediments, such as dry river and lake beds like the Bodele depression in Chad. Dust emissions exhibit large daily and interannual variability. Figure 4 shows the seasonal distributions of mineral dust optical depth. Emissions from deserts in the Sahara, Arabian Peninsula, and Iran peak in the summer. Deserts in Inner China emit in the spring. Smaller sources include deserts in southern Africa, Argentina, and Australia. The Sahara desert is the main contributor to global emissions. Cement production and related industrial activities also release mineral dust into the atmosphere, thus representing a small, anthropogenic source of mineral aerosols. Residence time of mineral aerosols is strongly dependent on their size: although the larger particles only reside for 1–2 days, smaller particles can remain in the atmosphere for over a week as evidenced by the deposition of mineral dust from the Sahara in the Caribbean and South America.

Figure 4 As Figure 2, but for mineral dust aerosols.

Figure 5 As Figure 2, but for marine aerosols.

Marine Aerosols

Aerosols produced at the ocean–atmosphere interface are dominated by sea-salt particles. Those aerosols are generated from breaking oceanic waves that are themselves driven by near-surface winds. As the seawater droplets emitted in the atmosphere evaporate, the salt concentration of the solution increases. Figure 5 shows the seasonal distributions of marine aerosol optical depth. In the Southern Hemisphere, the latitude band between 40 and 50° S is associated with the strong westerly winds called Roaring Forties and is a region of large sea-salt emissions. Sea-salt aerosol residence time in the atmosphere is typically short, less than a day, but can be longer in cloud-free oceanic regions with low precipitations.

Other aerosols are emitted at the air–sea interface. Firstly, some species of phytoplankton increase the concentrations of dimethylsulfide (DMS) in the ocean. This occurs in regions of high primary productivity, sufficient solar radiation, and shallow mixed-layer depth: high-latitude oceans of both hemispheres during the corresponding summer. DMS makes its way into the atmosphere and may be oxidized to sulfur dioxide, which in turn may form sulfate aerosols. Secondly, the ocean is a strong natural source of ammonia. Thirdly, sources of organic- and iodo-carbon aerosols from phytoplankton blooms and algae have recently been postulated, although their global emissions are currently unknown.

Fine-Mode Natural Aerosols

A variety of natural processes can emit aerosol precursors and fine-mode aerosols into the atmosphere. First, wild fires started by lightning emit biomass-burning aerosols, although those emissions are often counted together with the anthropogenic emissions due to the difficulty of determining the origin of forest fires. Fires are more likely in the local dry

season, and can be large in the boreal forests of Canada and Russia.

Vegetation produces pollens and bacteria that are in effect primary aerosol particles. The strength of those emissions is highly uncertain, but may represent several hundred teragrams per year. Plants also emit classes of VOCs called terpenes (from needle-leaf forests) and isoprenes (from broad-leaf forests) that can oxidize into secondary organic aerosols. The strength of those sources is also uncertain. Their seasonality is linked to the growing cycle of vegetation, with peak emissions from April to September in the Northern Hemisphere. Land-based natural ecosystems also emit ammonia and DMS.

Finally, although volcanoes are often viewed as a source of stratospheric aerosols, this is only true for the major explosive eruptions: Degassing volcanoes are a continuous source of sulfur dioxide in the troposphere, and minor eruptions emit volcanic ash plumes that can be a hazard to aviation.

Historical and Future Variations in Sources

Estimating past aerosol emissions is challenging, as there is virtually no observational basis. Empirical relationships in socio-economic, sector-based models are used to link aerosol emissions to changes in population and technologies. For future emissions, those models are used with prescribed scenarios of emission changes, experimenting with different assumptions on technological shifts, industrialization of developing countries, and population growth.

The industrial revolution has had a large impact on the sources of anthropogenic aerosols. From the middle of the nineteenth century in Europe and North America, emissions of sulfur dioxide and carbonaceous aerosols have increased steadily, at increased rates after the World War II. In Asia,

anthropogenic emissions started to increase in the middle of the twentieth century, and present emissions exceed European and American levels for some species like fossil fuel carbonaceous aerosols. Due to concerns in decreasing air quality and the impact of acid rains, emission controls for sulfur dioxide have been successfully implemented in most industrial countries, leading to decreases in sulfate aerosol concentrations. The decline of hazy conditions in Europe since the late 1970s has been linked to those aerosol decreases. However, they have been partially compensated by increases in nitrate aerosols driven by the increased use of fertilizers in agriculture. In the future, it is expected that stronger emission standards will decrease anthropogenic emissions further, although the industrialization of South America and Africa may lead to local increases.

Past biomass-burning emissions are likely to have been larger than present levels, as agricultural practices switched to synthetic fertilizers, and wild fires are now more efficiently suppressed. However, in countries where forest clearing dominates the emissions, those are assumed to have increased in line with the increase in population and are therefore larger in present days. Future changes in anthropogenic biomass-burning emissions are uncertain and depend on trends in population and agricultural technology changes.

Past and future emissions of natural aerosols depend on the variation of their driving factors like wind speed, vegetation and bare soil areas, temperature, soil moisture, and ocean biogeochemistry. Mineral dust emissions are expected to increase with desertification. Sea-salt emissions are expected to increase with the retreat of sea ice and the corresponding increase in areas of open ocean. Changes in ocean biogeochemistry and land vegetation and their impact on aerosol emissions are driven by near-surface temperature changes and are strongly linked to the hydrological cycle.

Long-Range Transport of Tropospheric Aerosols

Aerosols are transported away from source regions during the few days when they reside in the atmosphere. Consequently, a given region is affected not only by its local aerosol sources, but also by sources upwind. Long-range transport depends on the amount of aerosol emitted, weather systems, and aerosol chemistry, especially aging processes.

Transport occurs predominantly within the troposphere, either at low level in the boundary layer or aloft in the free troposphere. In midlatitude regions, transport is typically eastward with a smaller poleward component. Transport is driven by weather systems in winter and, especially over land, convective processes in summer. Both winds and precipitation are larger in winter than in summer, and influence long-range transport in opposite ways: stronger winds promote longer transport distances while larger precipitation reduces the aerosol residence time. Similar opposing effects occur when comparing low- and high-level transport. Winds are stronger aloft, especially in the jet streams, and accelerate the transport. However, wet deposition is also more powerful above the boundary layer, reducing residence times. Aerosol precursors can be transported away from their source, undergo oxidation during or at the end of the transport, and be received as secondary aerosols. The colder and drier conditions of the upper troposphere can enhance or inhibit the chemical reactions that form secondary aerosols, depending on the precursor. In the Tropics, vertical transport is driven by the rising and descending branches of the Hadley cell, and trade winds export the aerosols westward. Because atmosphere circulation is organized in relatively isolated cells, transport from the Tropics to the midlatitudes, and between the two hemispheres, is small. Figure 6 summarizes the winter and summer aerosol transport patterns.

In the Northern Hemisphere, North American aerosols are transported across the Atlantic toward Europe, European aerosols toward Central Asia and the Arctic, and aerosols from China are transported across the Pacific Ocean. Although local sources dominate anthropogenic aerosol concentrations, import from other regions due to long-range transport can still represent 30–40%.

Mineral dust transport from the Sahara is associated with a specific air layer, called the Saharan Air Layer, located at an altitude of about 6 km and characterized by warm temperatures and dry conditions. Mineral dust aerosols in that layer cross the Atlantic Ocean toward South America in winter and spring and, as the intertropical convergence zone moves northward, toward the Caribbean in summer. Mineral aerosols deposition in the ocean and the Amazon provides a large amount of nutrients (phosphorus, potassium, and iron) to marine and land ecosystems. On an annual average, deposition has been estimated at about 250 Tg in the Atlantic,

Figure 6 Summary of long-range aerosol transport as black arrows from the main aerosol sources, for north hemisphere winter (left) and summer (right). Background shows total aerosol optical depth at $0.55\ \mu\text{m}$ as derived from observations by the satellite-borne Moderate-resolution Imaging Spectroradiometer (left) and modeled in the Hadley Centre climate model HadGEM2-ES (right).

20–30 Tg in the Caribbean, and 15–25 Tg in the Amazon. Less frequently, mineral dust aerosols are transported across the North Atlantic or the Mediterranean toward Europe, such as depicted on [Figure 7](#).

Synopsis

Mineral aerosols (often referred to as dust) are ubiquitous in the atmosphere. Several sources contribute to the dust loading such as soil-derived wind-blown (aeolian) dust, industrial processes, and volcanic eruptions. This article deals with the major impacts of mineral dust as well as its sources and properties, emphasizing the dust radiative effects.

Introduction

Atmospheric mineral aerosol, often referred to as dust, plays multiple important roles in the Earth systems, affecting the radiative energy balance, hydrological and biogeochemical cycles, land and ocean ecosystems, and human health. This article discusses the sources, properties, and major impacts of mineral dust, with an emphasis on the dust radiative effects.

Dust Sources and Production Mechanisms

Covering about 33% of the global land area, arid and semiarid regions are the major source of wind-blown (aeolian) dust. The Sahara Desert in North Africa is the single world's largest dust producing region, while deserts in East Asia (China and Mongolia) are the second largest source. Other important dust source regions are located in the Middle East, Central Asia, Australia, southwestern United States, and northwestern India. Although there are various similarities between arid and semiarid regions, active dust sources exhibit significant spatial heterogeneity and differ in dust emission strength. To date, there is no general theory of why some regions are more efficient active dust sources than other regions.

The dust emission is the complex, nonlinear process, which is controlled by a combined effect of meteorological characteristics (especially near surface winds) and land surface properties. Vegetation, roughness, soil texture, mineralogy, and moisture of the land surface combine and determine the threshold wind speed required to initiate the motion of dust particles. Advanced parameterizations of the dust emission process allow predicting the threshold wind speed as a function of the land surface characteristics. However, a single value of the threshold wind speed, for instance 6.5 m s^{-1} at 10 m height, is often used in the general circulation models or regional models, mainly because of the lack of input data on surface properties at the global scale.

Once winds are higher than a threshold value, the movement of dust particles can be initiated either by aerodynamic forces (called suspension) or by the impact of saltating soil grains (a process known as bombardment). Only the finest particles with diameters below about $60 \mu\text{m}$ can be suspended directly and transported upward by turbulent eddies. Particles in this size range, however, make up only a small fraction of soil grains, most of which are present in the form of aggregates of larger sizes due to strong interparticle cohesive forces. The

aggregates typically have diameters from about 60 to $80 \mu\text{m}$ to several hundred micrometers. The bombardment-induced breakage of aggregates results in the release of fine particles, which is thought to be a major contributor to aeolian dust entrainment into the atmosphere.

The dependence of dust emission on the land surface characteristics suggests that the modification of land surface (for instance, by human activities) may affect the dust emission and hence alter dust load in the atmosphere. Various human activities (such as agriculture, construction, deforestation, etc.) lead to land surface disturbances. Disturbed surfaces are likely to be more efficient dust sources than natural undisturbed lands. The dust fraction produced as a result of human activities is called anthropogenic dust. Recent estimates show that anthropogenic dust could be as much as 30–50% of total dust load depending on a region, but this remains highly uncertain. In addition, climate variability or climate change may alter dust emissions. Frequent droughts and strong winds increase the generation of dust, while rains tend to inhibit it.

Dust Loadings in the Atmosphere

Dust is a major component of atmospheric aerosols in many parts of the world. Both observations and model simulations indicate that dust load exhibits a complex spatial (horizontal and vertical) and temporal distribution in the atmosphere. The atmospheric loading of dust is controlled by the source strength, dust production mechanism, and removal processes acting upon dust particles during the atmospheric transport.

First of all, initial dust emission has complex spatial and temporal variations because dust sources have a dispersed geographical distribution and their strengths vary with time. The duration of dust storms is typically a few days having pulses of strong winds (gusts) of several hours. In addition, the variability of atmospheric transport and size- and composition-dependent removal processes further contribute to the variability of dust load.

Long-range dust transport exhibits substantial seasonal and interannual variations that are controlled by both the atmospheric circulation and the hydrological cycle over a certain geographical region. In particular, precipitation, which is highly variable from year to year, may affect the atmospheric dust cycle by increasing (or decreasing) soil moisture and vegetation cover and suppressing (or promoting) dust emission. Precipitation events occurring along dust transport

pathways are the most efficient mechanism for removing dust particles from the atmosphere.

Despite the varying frequency and strength of dust events, they do occur each year. Also some seasonal dust emission and transport features are repeatable from year to year for certain dust source regions. For instance, the Sahara is an active dust source the whole year, while the transport of Saharan dust over the North Atlantic Ocean shifts northward from about 5° N during winter to about 20° N during summer. Asian dust outbreaks reach their maximum in spring when Asian dust can be transported as far as North America.

Much of our understanding of the large-scale dust distribution and transport rests largely on satellite remote sensing data. Dust plumes are readily observed in ultraviolet (UV), visible, and infrared (IR) channels of satellite instruments. Satellites provide the primary means of obtaining a global perspective of areal extent of dust plumes as well as some dust properties such as optical depth and effective particle size. [Figure 1](#) presents true color images taken by NASA Moderate Resolution Imaging Spectroradiometer, which illustrate representative dust outbreaks originating in Northern Africa (upper panel) and in Asia (lower panel).

Satellite passive instruments provide a column-integrated view of dust loadings in the atmosphere. Complementary space and ground-based lidar observations allow for characterization of the vertical distribution of dust. Measurements reveal that dust plumes often exhibit a complex multilayered structure. For instance, transport of Saharan dust occurs at higher altitudes in a layer that typically reaches 5–6 km, although one or several layers might be present below it. Concentrations aloft are usually several times greater than those in the marine boundary layer. Dust layers can be intermixed with layers of other aerosols or clouds.

Dust Properties

The mineralogical composition and particle size are the major properties of mineral aerosol governing its impacts upon the Earth's systems. Initially, the composition of soil grains and generation processes determine the particle size distribution of airborne dust particles, their composition, and the degree of particle aggregation. Both the particle size distribution and the composition can be altered during dust transport in the atmosphere, called dust aging.

The main species found in mineral dust are quartz, various clays (e.g., kaolinite, illite, montmorillonite), carbonates, feldspars, chlorites, and iron oxides (e.g., hematite, goethite) among others. These minerals are characterized by very different physical and chemical properties. For instance, different minerals have distinct abilities to adsorb water vapor and other chemically important atmospheric gases. Each mineral has distinct spectral optical constants (or refractive indices), which determine how dust particles scatter and absorb the electromagnetic radiation. Consequently, the properties of dust as a mixture are determined by the relative abundance of various minerals and their aggregates. However, numerous climate and remote sensing studies have considered dust as a single generic species. This is partly due to the complexity of quantitative determination of the mineralogical composition and a lack of data.

The dust composition is thought to vary from source to source. For instance, dust in the Sahelian region is characterized by a high Fe/Al ratio due to the abundance of ferrallitic soils. In contrast, soils in the semiarid regions of Central Asia contain less Fe. The difference in the amount of iron oxides is of special importance because they control primarily the ability of dust particles to absorb sunlight.

Dust particles cover a wide range of sizes from about a few tenths to several hundreds of micrometers. Coarse particles are quickly removed from the atmosphere, and the ones transported over long distances usually have sizes below 20 µm. Several size modes are commonly introduced to characterize the dust particle size distribution. Size modes may have different compositions. In general, clay particles tend to be smaller in size than those made of quartz or carbonates.

Near the source regions, dust concentrations may be as high as a few thousand particles per cubic centimeter during the dust storm. Gravitational settling and rainout are major removal processes affecting dust concentration and particle size distribution during long-range transport. Other important processes, shaping particle spectra and composition, are heterogeneous chemistry on dust particle surfaces, cloud processing of dust particles, and interactions with other atmospheric aerosols. All these processes control the lifetime (or residence time) of dust particles in the atmosphere, which is up to 2 weeks on average. Despite the relatively short lifespan, dust can be carried to great distances up to a few thousand kilometers, affecting large geographical regions. Frequently, Saharan dust plumes reach the Caribbean, the Gulf of Mexico, and the southeast coast of the United States, while Asian dust can be transported as far as the west coast of the United States. Although it is believed that long-range transported dust particles are mainly in the size range from about 0.05 to 20 µm, coarse particles of about 100 µm diameter have been measured at distances of several thousand kilometers from dust sources.

Dust particles exhibit a large variety of shapes, often occurring as irregular (nonspherical) minerals or aggregates of several minerals. To date, there is no generally accepted classification of dust particle morphologies and data are limited. As a necessity, a simplified assumption that dust particles have spherical or spheroidal shapes is often made.

The concentration, composition, size distribution, and morphology of dust particles determine their optical properties. Dust particles can scatter and absorb electromagnetic radiation in a wide range of wavelengths from UV to IR. The optical characteristics needed for radiative effect assessments are the optical depth, single scattering albedo, and scattering phase function. These characteristics are also functions of the location and time, because of varying properties of transported dust.

The optical depth of dust plumes is largest near the dust source and it decreases farther from the source being controlled largely by the dust concentrations. Over the oceans, the highest optical depths occur in regions influenced by dust transport. At visible wavelengths, optical depths as high as 10 have been measured during dust storms. It has a weak dependence on the wavelengths in the visible region, but various spectral features occur in the thermal IR. Observations of the dust optical depth in the thermal IR window region suggest that it is about 2–10 times smaller than in the visible region.

Figure 1 Representative dust outbreaks originating in Northern Africa (upper panel) and in Asia (lower panel). Images taken by the NASA Resolution Imaging Spectroradiometer.

The single scattering albedo, which is defined as the ratio of scattering and extinction coefficients, does not depend on particle concentration but rather on the particle composition, state of mixing, and sizes. It is a key optical characteristic that governs the heating or cooling impact of dust aerosols upon the Earth system. The single scattering albedo of dust is in the range from about 0.75 to 0.99 in the solar and is characterized by strong wavelength dependence, increasing from UV to near-IR. The single scattering albedo may vary during the transport as dust ages. If dust particles are coated by other aerosol species, they may have drastically different properties from those that are evident at the dust source.

Although the scattering phase function of dust particles is crucial for remote sensing applications, there are only a few actual measurements. Therefore, this and other optical characteristics of dust are often computed by applying Mie theory for a certain size distribution and refractive index. More advanced numerical codes allow optical computation of nonspherical shapes. The T-matrix method is the most common approach for computing the optical characteristics of spheroidal shapes, while the discrete dipole approximation models for particles of any morphology.

Dust Effects

Mineral dust particles, by virtue of their chemical, physical, and optical properties, cause various impacts upon the atmosphere, environment, human, and overall Earth's system. [Table 1](#) lists some major impacts of dust and their importance. Many important impacts involve interactions of mineral aerosol with solar and IR radiation. Dust-induced perturbations to the radiative energy distribution have a significant impact on the surface energy balance and the planetary (global) energy balance, with implications for the regional and global climate. In contrast to greenhouse gases, dust may cause either a positive or negative total (solar plus IR) direct radiative forcing at the top of the atmosphere, depending on dust optical properties, atmospheric conditions, and surface reflectance. The radiative forcing and

heating/cooling rates of dust may be of different signs in the solar and IR regions. Dust reduces the solar irradiance reaching the surface and increases longwave radiation by a lesser amount, so the net surface radiative balance decreases.

The direct radiative forcing of dust has a complex geographical distribution because the dust sources and sinks are not uniformly distributed and the lifetime of mineral particles is short in the atmosphere. Thus, the presence of dust may enhance greenhouse gas warming in some regions and oppose it in others. In addition, dust may affect Earth's radiation balance indirectly by altering the properties, amount, and distribution of clouds. These are termed as indirect radiative effects. Dust particles can serve as cloud condensation nuclei (CCN) or ice nuclei (IN), affecting water, ice, and mixed-phase clouds. The ability of dust particles to serve as CCN or IN strongly depends on the mineralogical composition and particle size. Additional influence of dust on the energy and hydrological cycle proceeds through dust deposition on snow-covered surfaces, resulting in decreased surface reflectivity while promoting snowmelt.

Dust also affects the radiatively important gases and other aerosol species through several physicochemical mechanisms. By altering UV radiation, dust influences photolysis rates and hence the photochemical formation of such a radiatively important species like ozone. Dust particles have a high surface area per unit mass, which makes them ideal sites for heterogeneous chemical reactions. Some atmospheric gases (e.g., nitric acid) can directly condense on dust particles. These mechanisms provide a plausible explanation of the elevated sulfate and nitrate levels associated with dust particles that have been observed over both the Pacific Ocean and Atlantic Ocean. Overall, the impact of dust on atmospheric chemistry depends on dust particle composition and size, concentrations of gaseous species, as well as ambient conditions (e.g., temperature and relative humidity).

Dust has a considerable impact on the chemical and biological processes occurring in land and ocean ecosystems. Light is a vital factor governing plant photosynthetic activities. By altering the photosynthetically active radiation (400–700 nm), dust affects the terrestrial vegetation functioning, with implications for the carbon cycle. Deposited dust may supply

Table 1 Major impacts caused by dust aerosol and their importance

<i>Impact</i>	<i>Importance</i>
Direct radiative impacts	
Causes radiative forcing at the top of the atmosphere	Affects energy balance of the Earth's climate system
Causes radiative forcing at the surface	Affects surface temperature and surface–air exchange processes
Causes radiative heating/cooling within a dust layer	Affects temperature profile and atmospheric dynamics
Affects visibility	Decreases visibility, posing a traffic hazard
Impacts on clouds	
Serves as ice nuclei	Affects the properties and amount of ice clouds

Transports nutrients (iron and phosphorous)	Affects biogeochemical processes

nutrients to ecosystems. Soluble iron supplied by dust particles deposited in the oceans is essential for the growth of phytoplankton. The transport of micronutrients (such as phosphate and potassium) associated with dust has been recognized for its importance to terrestrial ecosystems.

The degradation of visibility and health problems caused by dust make it an important air quality issue. Dust particles are toxic or can act as the transport mechanism for toxic species, which can be inhaled and pose a health threat.

Although the importance of dust in the Earth's system has been well recognized, quantitative assessment of the dust impacts still poses significant challenges. Improved understanding of the dust properties and governing processes will be needed to decrease the current uncertainties. This has been an active field of research, especially in the past few decades.

Introduction

Atmospheric aerosols consist of a suspension of solid or liquid particles in air. These particles range from molecular clusters less than one nanometer in diameter to pollens, wind-blown soil dust and sea salt of 10 μm or larger. Figure 1 shows an idealized atmospheric aerosol size distribution with the characteristic modes in which particles tend to be found. Homogeneous nucleation leads to the clustering of molecules that grow to particles several nanometers in diameter at the small end of the spectrum. Aitken or nuclei mode particles in the 10 to 100 nm diameter range often contain 'primary' particles that are directly emitted into the atmosphere by combustion processes. Accumulation mode particles contain most of the submicron mass. Most of this mass is typically 'secondary' in origin (i.e., formed in the atmosphere by chemical transformations). Sulfates, nitrates, and organics typically comprise most of the accumulation mode mass, and this mass can accumulate in different submodes, depending on the chemical mechanisms by which they are formed. Coarse-mode particles tend to be produced by mechanical processes.

(Figure 2(a)–(c)) show photographs of atmospheric particles obtained by electron microscopy. The chain-agglomerate soot particle in (Figure 2(a)) is typical of particles emitted by diesel engines or other combustion sources. (Figure 2(b) and (c)) illustrate particles of mixed composition. The salt in (Figure 2(b)) was probably emitted directly into the atmosphere as sea spray, while the sulfate crystals attached to it may

Figure 1 Idealized atmospheric aerosol size distribution. Particles tend to be found in modes that reflect the different processes by which they are formed in the atmosphere by chemical transformations or are emitted directly into the atmosphere from sources.

have been produced in the atmosphere by chemical transformations. The rutile in (Figure 2(c)) probably originated as wind-blown dust and may have accumulated the sulfate coating as a result of atmospheric processing. The variabilities in shape and composition illustrated by the photographs in (Figure 2(a)–(c)) introduce ambiguities in aerosol measurements since the responses of particle measuring instruments depend on such properties. In addition, particles often contain volatile or semivolatile species such as water, nitric acid, ammonia, and various organic compounds that are also present in the gas phase. This adds another challenge to obtaining accurate measurements, since such species undergo continuous exchange between the condensed and gas phases, and the gas/particle distribution can be perturbed during sampling.

This article summarizes the most important methods for measuring atmospheric aerosols. It first discusses aerosol sampling and chemical analysis of aerosol, then concludes with methods used to measure physical properties of particles such as particle size and number concentration. Throughout, discussion focuses on *in situ* particle measurements; a great deal of valuable information on global distributions of aerosols has been obtained with satellites, but such measurements are not discussed here (see **Satellites and Satellite Remote Sensing: Aerosol Measurements**).

Sampling

Accurate aerosol measurements require the collection of a representative sample. Obtaining representative samples of particles smaller than 1 μm is usually not too difficult. Under typical sampling conditions particles in this size range travel with the gas. Difficulties may be encountered with particles smaller than about 10 nm in diameter since, because of their high diffusivities, they can be lost on the walls of sampling tubes during transport to the detector. It is usually possible to design sampling systems that minimize this effect.

Supermicron particles are difficult to sample. Such particles have so much inertia that they tend not to follow the gas flow as it enters the sampler. Figure 3 shows trajectories of large particles as they are drawn into an aerosol sampler. When the wind speed exceeds the velocity of the air flow into the sampling tube (subisokinetic sampling), the sampled concentration exceeds the true ambient concentration (Figure 3(a)), while the reverse is true when the wind speed is less than the sampling speed (superisokinetic sampling; Figure 3(b)). An ideal *isokinetic* sampler is aligned with the wind and draws in air at a speed equal to the wind speed. In practice, wind speeds and directions vary, so achieving this ideal with samplers at a fixed location is impractical.

It might appear that an aircraft would provide an ideal platform for sampling coarse particles. Isokinetic sampling

Figure 2 Photographs of atmospheric particles obtained by transmission electron microscopy. (a) Chain agglomerate soot particle. (b) Sulfate attached to a sodium chloride particle. (c) Mineral dust particle coated with sulfate. would be achieved automatically if the sampler pointed straight ahead and sampled at a velocity equal to the aircraft velocity. Unfortunately, this is not the case. Even if the probe sampling velocity equals the aircraft speed, variations in the aircraft orientation lead to misalignment between the probe and the sampled airstream, and the high sampling velocities required lead to turbulent deposition of particles within the

sampling probe. Thus, it can be difficult to transport particles through the probe to the measuring instrumentation. The design of aircraft sampling inlets that deliver a known fraction of larger particles is a current area of research.

Omnidirectional sampling inlets are typically used for fixed-point sampling. Such inlets draw aerosol from all directions through a horizontal annular opening. Sampling efficiencies

Figure 3 Trajectories of large particles as they are drawn into an aerosol sampling probe. (a) Subisokinetic sampling occurs when the velocity of the sampled aerosol at the probe entrance is less than the velocity of the wind relative to the probe. In this case the concentration of 'large' particles in the sampled aerosol is higher than the ambient concentration. (b) For superisokinetic sampling, the sampled concentration is less than the true concentration.

for omnidirectional inlets are independent of wind speed, and can be nearly 100% for particles up to 10 μm .

In summary, obtaining representative aerosol samples for particles smaller than a few micrometers in diameter is usually straightforward. Obtaining representative samples for particles larger than this is difficult since, owing to their inertia, large particles tend not to follow air as it flows into a sampler.

Sample Collection and Analysis: Filters and Impactors

Filters are the device most commonly used for collecting particles for analysis. Samples are collected by removing particles from a known volume of air, and are analyzed for particulate mass or species concentrations. Electron micrographs of several types of filter media commonly used to sample atmospheric particles are shown in (Figure 4(a)–(c)). All of these media contain passages through which the gas flows and solid substrates on which particles are collected.

Filters collect particles by three different mechanisms, as illustrated in (Figure 5). Very small particles (diameter less than about 0.1 μm) are collected by diffusion, and because diffusivities increase with decreasing size, particle collection efficiencies increase with decreasing size. Large particles (diameter $> \sim 1 \mu\text{m}$) are collected when, due to their inertia, they are unable to follow the gas as it flows around a solid surface (e.g., a fiber) and impact on the fiber. Because inertia increases with increasing particle size, filter collection efficiencies increase with size in this range. Intermediate-sized particles are collected by interception when the gas flow carries them to within one particle radius of the filter medium. Note that 'sieving' is not a significant particle collection mechanism for

air particle filters; as can be seen in (Figure 4), the dimensions of the air passages through the filter are typically much larger than the sizes of the collected particles. All filters have a 'most penetrating size' that falls typically in the 0.05 to 0.3 μm diameter range, where particle collection by diffusion, interception, and impaction reaches a minimum. For filters typically used for air filtration, however, collection efficiencies even at this size usually exceed 99%. Therefore, it is generally reasonable to assume that all particles delivered to the filter are collected. Filters are typically operated downstream of an inlet that removes all particles larger than a specified size.

Substantial effort has been made to develop diffusion denuder filter samplers for measuring the gas and particle phase concentrations of semivolatile species. The design of such samplers for inorganic species including ammonium nitrate is well developed, and work is underway to extend this methodology to various organic compounds. Sampling such compounds presents a challenge because they can volatilize from the filter during sampling, thereby leading to an underestimate of the particle-borne concentration. A schematic of a diffusion denuder sampler is shown in Figure 6. The aerosol is first drawn through an annular denuder, the walls of which are coated with a chemical that reacts readily with the gas to be removed. Basic compounds such as sodium carbonate are often used to remove acidic gases such as sulfur dioxide and nitric acid, and acidic compounds such as citric acid are used for ammonia. Owing to their high diffusivities, gases diffuse to the coated walls and are removed with nearly 100% efficiency. Particle diffusivities are orders of magnitude lower than those for gases, so particles pass through the denuders to a filter where they are collected with nearly 100% efficiency. Volatilization from the collected particles occurs during sampling, and a suitable collector is located downstream of the filter to collect these volatilized compounds. For example, nylon filters are known to collect nitric acid vapor with nearly 100% efficiency, and porous polyurethane foam is used to collect certain organic vapors. The particle phase concentration of the semivolatile compound is found by adding the loadings collected by the filter and the downstream adsorber. Several different approaches are used to measure the gas phase concentration. In some cases the collected gas can be extracted from the diffusion denuder and analyzed directly. Alternatively, two samplers can be operated in parallel, one with a diffusion denuder and one without. The sampler without the diffusion denuder collects the total gas-plus-particle concentration. The gas phase is then determined by difference.

Cascade impactors are used to collect size-segregated samples for subsequent analysis. A schematic diagram of a cascade impactor is shown in Figure 7. The aerosol is first accelerated through a large nozzle towards a collection substrate that deflects the air and collects the largest particles by inertia. The aerosol is then transported to a stage with a slightly smaller nozzle that collects smaller particles due to the higher speed of the gas through the nozzle. Impactors can provide a very sharp size separation down to sizes as small as 10 nm. Measurements of solid particles can be adversely affected by bounce, which can be reduced by greasing the collection substrates. A limitation of impactors is that no strategy has been developed to measure evaporative losses of semivolatile compounds from the individual impactor stages.

Figure 4 Electron micrographs of several types of filter media commonly used to sample atmospheric particles. The filter media illustrated in these figures include (a) a 3.0 μm Teflon membrane filter, (b) a glass fiber filter, and (c) a 1.0 μm polycarbonate membrane nuclepore filter. Courtesy of Professor Benjamin Y. H. Liu, Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN.

Virtual impactors replace the collection substrate with a receiving tube that draws a small fraction of the flow and into which all particles larger than the cut size are projected. Virtual impactors avoid bounce and use conventional filter substrates, but have the disadvantages that they cannot be designed with cut points that are as sharp or as small as can be achieved with conventional impactors. Cascade impactors segregate particles according to aerodynamic diameter, which depends on shape, physical size, and particle density. Samples collected with filters or impactors are typically analyzed to determine particulate mass or species concentrations. [Table 1](#) provides a summary of typical minimum detection limits that can be achieved by commonly used analytical methods.

Real-Time, *In-Situ* Analysis of Aerosol Chemical Properties

Filtration with subsequent analysis in the laboratory is by far the most commonly used approach for determining the composition of atmospheric aerosols. Considerable progress has been made in the last few years, however, on techniques that provide real-time information on aerosol composition. For example, particles can be collected directly in liquid water and analyzed by ion chromatography to determine concentrations of major aqueous ions, including sulfate, nitrate, ammonium, chloride, etc. When employing denuders these methods can also be used to measure gas phase concentrations

Figure 5 Filters collect particles by three different mechanisms. Diffusion is primarily responsible for the collection of particles smaller than about $0.1\ \mu\text{m}$. Inertial impaction, which causes particles to cross air streamlines and deposit on the filter substrate, is responsible for the collection of particles larger than about $1\ \mu\text{m}$. Interception, which occurs when the air streamline brings a particle to within one particle radius of a filter substrate, is important for particles in the intermediate size range.

of semivolatile compounds. Other approaches involve collecting particles by impaction on a substrate from which they can be volatilized by rapid heating and analyzed by a conventional gas analyzer. These semicontinuous samplers provide species concentrations with a time resolution down to 3 min and show that aerosol concentrations often vary significantly over time scales required for filter samples.

A tremendously exciting new development in aerosol measurement involves the use of mass spectrometry to measure the composition of individual particles in real time. Particles are drawn through an inlet into a low-pressure chamber where they are volatilized and ionized by a high-intensity laser pulse. The ions are analyzed by time-of-flight mass spectrometry to determine particle composition. A schematic diagram of one such instrument is shown in (Figure 8). It is not yet clear that instruments of this type will be able to provide quantitative information on species mass concentrations. They do, however, provide rich new insights into the origins of various particle types and also provide insights into chemical transformations that occur on and within particles in the atmosphere. For example, (Figure 9) illustrates the type of information that can be obtained from such measurements. In this study nearly half of the elements in the periodic table were detected in particles sampled from an aircraft between 5 and 19 km altitude.

Measurement of Physical Properties

Instrumentation for measuring aerosol physical properties can be divided into two major categories: those used to measure a single overall property of the aerosol and those used to

Figure 6 Schematic of a diffusion denuder sampler for collecting the gas and particle phases of semivolatile compounds.

Figure 7 Schematic diagram of a cascade impactor. These instruments separate particles into several different size fractions for subsequent measurement of size-resolved mass or species concentrations.

measure aerosol size distributions. Examples of overall properties (also referred to as integral properties) are the total number concentration of particles of all sizes or the total amount of light scattered by particles of all sizes. Instruments that measure integral properties are often easy to operate and provide data that are straightforward to interpret. A limitation of such measurements is that they cannot be used in a simple way to determine other aerosol properties. In principle, a detailed and accurate measurement of the aerosol size distribution can be used to determine any integral property of the aerosol. Such data, however, are difficult to acquire and analyze and are subject to uncertainties owing to the dependence of instrument response on aerosol properties including shape, density, and refractive index, which are often not known precisely.

Measurements of Integral Properties

Condensation particle counters (CPCs) have been used since John Aitken invented them in the late 1800s to measure total

concentrations of aerosol particles. (CPCs are also referred to as condensation nuclei counters (CNCs) and Aitken nuclei counters.) They function by exposing particles to a supersaturated vapor which causes them to grow by condensation to a size greater than $1\text{ }\mu\text{m}$, which can easily be detected by light scattering. Concentrations are then determined either by counting the pulses of light scattered by individual droplets as they flow through the scattering volume of an optical detector (**Figure 10**) or from the light attenuation or scattering produced by the cloud of droplets following condensation (**Figure 11**). An advantage of the single particle counting instruments is that concentrations are determined directly from the counting rate and the aerosol flow rate through the detector; no empirical calibration is required. The optical attenuation or scattering methods require an empirical calibration to determine the relationship between attenuation and concentration. The largest particle size that can be detected by a CPC is determined by transport into the condenser: because of their inertia, particles bigger than a few micrometers in diameter tend to be lost as they flow into the instrument. CPCs have been designed that detect particles as small as 3 nm , although a minimum detectable size of 5 to 10 nm is more typical. Recent work has shown that gaseous ions (i.e., molecules or molecular clusters that carry an elementary charge) smaller than 1 nm can be detected with a CPC.

Another aerosol integral property of considerable interest is the total amount of light scattered by particles. Light scattering is responsible for the hazy appearance of air in polluted regions (**Figure 12**) and is the most sensitive indicator of air pollution. Gases also scatter light by a process referred to as Rayleigh scattering. Rayleigh scattering is responsible for the blue color of the sky, and in a particle-free atmosphere would limit visibilities to about 300 km at sea level. On a per unit mass basis, however, particles are orders of magnitude more effective than gases at scattering light, and light scattering efficiency (the amount of light scattered per unit mass) reaches a maximum for particles between 0.1 and $1\text{ }\mu\text{m}$ where most secondary pollutant particles accumulate (**Figure 13**). This juxtaposition of light scattering efficiencies with the peak in the accumulation mode mass distribution (see **Figure 1**) causes light scattering to be the most sensitive indicator of polluted air. Integrating nephelometers are used to measure the total amount of light scattered by aerosol particles. The response of integrating nephelometers depends on the frequency distribution of the illuminating radiation, on the frequency response of the optical detector, and on the solid angle over which light scattering is collected.

Current air quality standards for particulate matter are based mostly on the total mass concentration of particles smaller than a specified size. For example, since 1987 the 'PM₁₀' National Ambient Air Quality Standard for particulate matter in the United States has stipulated that mass concentrations of particles smaller than $10\text{ }\mu\text{m}$ aerodynamic diameter cannot exceed $75\text{ }\mu\text{g m}^{-3}$ on an annual basis or $260\text{ }\mu\text{g m}^{-3}$ for 24 hours. The usual approach for measuring such mass concentrations is to determine the change in the mass of a filter that has removed particles from a known volume of air. Sampling times ranging from hours to a day or more are typically required for such gravimetric analyses, so such

measurements provide no information on variabilities in mass concentrations that occur during the sampling period. Furthermore, in regions with significant concentrations of semivolatile compounds such as ammonium nitrate and certain particulate organic compounds, filter measurements can be compromised by volatilization losses. For these reasons aerosol scientists have attempted to develop alternative

measurement techniques. These approaches include the measurement of the attenuation of 0.01 to 0.1 μeV beta particles through particulate deposits collected on filters, the change in the natural frequency of a piezoelectric crystal on which particles have been collected, the change in pressure drop across a filter on which particles are being collected, and the change in the natural frequency of a harmonic oscillating

Figure 8 Schematic diagram of a mass spectrometer for determining the composition of individual aerosol particles. Particle size is determined by measuring particle velocity in the particle sizing region of the instrument. Size depends on velocity because large particles, owing to their inertia, are not accelerated as rapidly as small particles as they flow from the aerosol inlet into the low-pressure regions of the instrument. Particle composition is determined by using time-of-flight mass spectrometry to measure the mass spectra of ions produced when the particles are volatilized by a high intensity pulsed laser. Figure 10 Continuous flow condensation particle counter (CPC). The aerosol is saturated with a vapor (butanol is commonly used) before it flows through a cooled cylindrical tube where the vapor becomes supersaturated and condenses on particles, causing them to grow to a size that is easily detected by light scattering. Courtesy of TSI, Inc.

Figure 11 Schematic diagram of the Model 1957 Pollak expansion-type condensation nucleus counter, a classic instrument of its type. An aerosol sample is drawn into the cylindrical chamber and brought with the pump to a pressure 1.21 times local atmospheric pressure. After allowing about 45 s for the aerosol to become saturated with water vapor from the wetted walls, the release valve is opened, permitting the aerosol to expand. The cooling caused by this adiabatic expansion leads to supersaturation of the water vapor and condensational growth of particles. The particle concentration is determined from the attenuation of light through the instrument caused by the aerosol cloud.

element on which a filter for collecting particles is mounted (Figure 14). Each of these techniques has limitations, but they all provide valuable real-time information that cannot be obtained with traditional gravimetric methods.

Measurements of Size Distributions

Instrumentation to measure aerosol size distributions down to 3 nm diameter has advanced significantly in the past two

decades. The most common sizing methods involve classification according to electrical mobility, the measurement of the amount of light scattered by individual particles, and the measurement of the terminal velocity to which particles are accelerated as they flow through a nozzle.

As a rule of thumb, a given instrument can measure the size distribution of particles ranging over about a factor of ten in particle diameter. One reason for this limitation is that concentrations of particles vary so significantly with size. This

Figure 12 View to the north from Keck Laboratory at the California Institute of Technology on a clear and a smoggy day. Photographs by the author.

Figure 14 Tapered Element Oscillating Microbalance (TEOM) for continuous measurements of particle mass concentrations. Aerosol is drawn through the filter, which increases in mass as particles are collected. As the filter mass increases, the natural oscillating frequency of the tapered element changes. The mass of particles on the filter is inferred from measurements of this frequency. Courtesy of Rupprecht Patashnick Co., Inc.

Table 2 Nominal particle counting rates in different size ranges for an instrument sampling at 1 liter per minute for a typical urban Los Angeles aerosol

Size range	Nominal sampling rate (particles s^{-1})	Sampling time required for 1% accuracy (s)
0.05–0.1 μm	10^6	0.01
0.1–0.2 μm	10^5	0.1
0.2–0.5 μm	10^4	1.0
0.5–1.0 μm	10^3	10
1.0–2.0 μm	10^2	100
2.0–5.0 μm	10^1	1000

can best be illustrated by considering, as an example, the typical urban Los Angeles aerosol. (Table 2) shows the rates at which particles in several size ranges would have been drawn into an instrument that samples air at 1 liter per minute. Because small particles are so much more abundant than large ones, they are sampled at a much higher rate. Therefore, the time required to collect a statistically significant sample increases sharply with size. The measurement protocol might call for measurements with a time resolution of, say, one minute. This can be achieved best by measuring large particles with high-flow instruments and small particles with low-flow instruments so that statistically significant samples can be achieved for all sizes in comparable time periods. Furthermore, because detection sensitivity depends on size, it is unlikely that a given detection scheme can be used over the entire size range of interest.

Electrical mobility analyzers are used to measure size distributions of particles ranging from about 3 nm to 0.5 μm .

Figure 16 Numerically calculated responses of a laser optical particle counter (OPC) to spherical carbon and sulfuric particles as a function of size. Notice that above 0.7 μm , sulfuric acid particles of three different sizes can produce the same instrument response. The different responses to carbon and sulfuric acid are due to the effect of refractive index on light scattering. Courtesy of Professor W. Szymanski, Department of Physics, University of Vienna, Vienna, Austria.

A schematic of a scanning mobility particle spectrometer (SMPS) commonly used for such measurements is shown in (Figure 15). The aerosol is brought to a Boltzmann equilibrium charge distribution by exposing particles to a high concentration of mixed positive and negative gaseous ions. At Boltzmann equilibrium the most common charge state is

Figure 15 Schematic of a scanning mobility particle spectrometer (SMPS) used to measure size distributions in the ~ 10 nm to 500 nm diameter range. The particle size in the sample flow at the bottom of the instrument is changed by varying the voltage applied to the center cylindrical rod. Size distributions are found by measuring the concentration of classified particles over a range of classifying voltages.

neutral. However, a statistically predictable fraction of particles contains ± 1 , ± 2 , ± 3 , etc. charges, and this distribution varies with particle size. Particles smaller than roughly 50 nm contain very few multiply charged particles, while particles of 0.5 μm contain more multiply charged than singly charged particles.

After the aerosol charge distribution has been adjusted the aerosol flows into the differential mobility analyzer (DMA), which is the heart of the SMPS. The DMA classifies particles according to their electrical mobility by flowing the aerosol through an annular gap between two coaxial cylindrical electrodes. The laminar flow between these electrodes includes the aerosol-containing flow, which enters along the inner wall of the outer cylinder and typically accounts for about 10% of the total flow, and particle-free sheath flow, which occupies the inner portion of the annulus. The outer electrode is maintained at ground while a voltage is applied to the inner electrode. If the center rod is positively charged then negatively charged particles migrate radially towards the inner electrode as the flow draws them axially through the annulus. Particles with high

electrical mobility deposit on the inner electrode, while those with low electrical mobility exit the DMA with the excess air. Particles in a narrow range of electrical mobilities exit the DMA through a narrow gap on the inner electrode and travel downstream to a detector, typically a condensation particle counter. Size distributions are obtained by measuring the concentration downstream of the DMA over a range of classifying voltages so as to cover a range of electrical mobilities. Electrical mobility depends on particle charge, geometric size, and shape; the electrical mobility size of a spherical particle equals its geometric size. Uncertainties in measured size distributions occur when a significant fraction of the measured particles are nonspherical. 'Inverting' the raw data to obtain size distributions requires taking into account the multiplicity of sizes that are obtained at any given classifying voltage, since particles of a given mobility can contain one or more elementary charges.

Optical particle counters (OPCs) are used to measure size distributions of particles as small as 50 nm, although a lower size limit of 0.1 to 0.3 μm is more typical. OPCs function by

Figure 17 Schematic of an aerodynamic particle sizer (APS). Particles are accelerated through a nozzle to a velocity that decreases with increasing particle size due to particle inertia. Size is inferred from velocity, which is determined from the time required for the particle to travel between the two scattering regions formed from the split laser beam. Courtesy of TSI, Inc.

passing particles through a small 'scattering volume' into which an intense source of light has been focused. As particles pass through the scattering volume they scatter light, which is collected by mirrors and sent to an optical detector which converts the scattered light to a voltage pulse that varies in proportion to the intensity of the scattered light. Size distributions are obtained by first establishing the relationship between pulse height and particle size for particles of known size and composition. Using this calibration, measured pulse height distributions for unknown aerosols can be 'inverted' to obtain size distributions.

The amount of light scattered by a particle depends on its refractive index and on its geometric size and shape. For any given particle, the amount of light scattered can depend on the solid angle over which scattered light is collected in a complicated manner, and particles of different sizes can produce the same OPC response. The response of a laser OPC to spherical carbon and sulfuric acid particles of known geometric size is shown in [Figure 16](#). The multivalued relationship between response and particle size seen for the sulfuric acid (e.g., the same response occurs for particles of 0.9, 1.4, and 1.8 μm) is less pronounced when particles scatter incandescent light, since the optical resonances that lead to the oscillations shown in [Figure 16](#) are wavelength-dependent and lead to a more nearly monotonic response when averaged over a broad distribution of wavelengths.

Aerodynamic particle sizers (APSs) ([Figure 17](#)) also use light scattering to determine particle size. The size measuring principle, however, is quite different from that employed with an OPC. In an APS, particles are accelerated through a nozzle and then pass through two focused laser beams that intersect the particle beam at right angles. A light-scattering pulse is obtained as particles pass through each of the lasers, and the particle velocity is determined from the known distance between the lasers and the time required to traverse this distance. Because of their inertia, large particles tend to lag behind the carrier gas as it accelerates through the nozzle, and they achieve a terminal velocity less than the gas-velocity. As particle size decreases, particles accelerate more readily with the gas. Therefore, the terminal particle speed approaches that of the gas. APSs infer particle size from the measurement of the particle's terminal speed. As with impactors, which also classify particles according to

aerodynamic size, measurements depend on the particle's geometric size, shape, and density.

Summary

Recent interest in the effects of environmental aerosols on radiative transfer through the atmosphere and on human health have led to significant advances in instrumentation for measuring aerosol physical and chemical properties. It is now possible, for example, to measure physical size distributions down to 3 nm diameter with a time resolution of several minutes, and instruments for measuring the composition of individual particles in real time are being developed and used for atmospheric studies. While most measurements of aerosol composition to date have involved the analysis of samples collected on filters, instruments are currently being developed that provide real-time information on aerosol composition with a much better time resolution than can be obtained with filters. These advances are leading to significant refinements in our understanding of the origins of atmospheric particles and of the role they play in atmospheric chemistry.

Synopsis

Atmospheric aerosols (i.e., particles suspended in air) interact with shortwave radiation from the sun and longwave thermal radiation from the Earth. These interactions profoundly influence the energy budget and climate of the planet. In this article, we first present a theoretical framework for quantifying aerosol–radiation interactions. We then discuss the global quantification of aerosol properties using sensors on satellites that measure upwelling radiation, along with metrics that can be used to estimate global impacts of aerosol–radiation interactions. Finally, we conclude with a discussion on new frontiers in global measurement of aerosol properties relevant for better understanding the role of aerosols on climate.

Introduction

Aerosols suspended in the Earth's atmosphere interact with light incident from the Sun and with terrestrial thermal radiation. The study of these interactions is important for understanding the present and future climate system. Naturally occurring aerosols reflect some of the incident solar radiation back to space before it can be absorbed and converted to heat: these include dust, sea salt, and stratospheric sulfate aerosols formed during volcanic eruptions. Anthropogenic aerosols released by the combustion of biomass and fossil fuels increase both the reflection of solar radiation back to space and its absorption within the Earth's atmosphere. It is necessary to include the radiative effects of aerosols in modern climate models in order to simulate recent changes in global surface temperature with reasonable fidelity.

For radiation incident on an aerosol particle, the two fundamental interactions are scattering and absorption. The combination of scattering and absorption is termed extinction.

Scattering is the deflection of an electromagnetic wave from its original direction of propagation. In geometrical optics, scattering occurs when the wave propagates through a mixture of media with different indices of refraction, for example, aerosols suspended in air. The index of refraction is the ratio of the speed of light in vacuum to that in a given medium. In a more familiar setting, the difference in the indices of refraction for air and glass is responsible for the focusing effect of lenses.

Absorption is the conversion of electromagnetic energy into internal motions of molecules within the aerosol. The molecules can rotate and vibrate in discrete modes determined by quantum mechanics. The amount of rotational or vibrational energy in each mode corresponds to a particular frequency of light. The frequency of light is the number of oscillations in the electromagnetic wave per unit time, and for visible light the frequency corresponds to color. When the frequency of radiation incident on an aerosol corresponds to the quantum modes of the aerosol molecules, some of the radiation is converted into internal energy. Aerosols can also emit thermal radiation following Kirchhoff's laws for the equilibrium between matter and radiation at constant temperature. The amount of thermal energy emitted from an aerosol particle at each frequency is governed by Planck's theory. Due to the moderate temperatures

in the Earth's atmosphere, almost all of the thermal radiation is emitted at infrared wavelengths. The emission of light from the Sun is also governed by Planck's theory, although the emission temperature is approximately 5770 K, corresponding to higher frequency (and lower wavelength) radiation than that of terrestrial radiation.

The interaction of aerosols with sunlight and terrestrial radiation can be calculated using Maxwell's equations for electromagnetic radiation. These equations may be written in an approximate form for radiation propagating through a mixture of gases, aerosols, and clouds. The equations are supplemented with Planck's theory for the emission of light, the optical properties of atmospheric constituents, and data on the distribution and concentrations of these constituents. The solutions quantify the effects of natural and anthropogenic aerosols on the net energy balance of the planet, the radiant energy absorbed in the atmosphere, and the sunlight and thermal radiation incident on the Earth's surface.

Scattering and Absorption of Light

Beer's Law for Direct Sunlight

Solar radiation incident at the top of atmosphere (TOA) can be treated as a traveling plane wave normal to the line between the centers of the Earth and the Sun. The solar radiation propagating through the atmosphere can be partitioned into direct and diffuse radiation. Direct radiation is the beam of sunlight that has not interacted with the constituents of the atmosphere or the Earth's surface. Diffuse radiation is sunlight that has been scattered by atmospheric constituents and/or by the surface. Direct radiation is converted to diffuse radiation when it first scatters from an atmospheric component or from the surface.

As direct radiation propagates from the tenuous upper atmosphere to the dense lower atmosphere, its intensity is reduced by both scattering and absorption. The basic principle governing the extinction of the direct beam is known as Beer's law or as the Beer–Bouguer–Lambert law. The principle states that the extinction through an optical medium is linear in the intensity of radiation incident upon that medium. For simplicity, only the effects of aerosols will be considered. Let ν denote the frequency of light in units of inverse time. Let $I_d(\nu)$

represent the intensity of direct solar radiation at a frequency ν . It is expressed in units of energy per unit frequency interval, time, area, and solid angle. The solid angle is a measure of the directions in which the wave is propagating. Let z denote the distance from the TOA. In mathematical form, Beer's law is given by eqn [1].

$$\frac{dI_d(\nu)}{dz} = -\rho k_e(\nu) I_d(\nu) \quad [1]$$

Here ρ is the density of the aerosols in units of mass per unit volume of air and $k_e(\nu)$ is the specific extinction in units of area per unit mass of aerosol.

The specific extinction is determined by the chemical composition of the aerosols and by the number of aerosol particles of different sizes per unit volume (a.k.a. the aerosol size distribution). For spherical aerosol particles, the extinction may be computed using Mie theory. Mie theory is often applied to nonspherical particles as a first approximation, for example, dust particles and complex chains of carbon compounds. The extinction is the sum of the effects of scattering and absorption denoted by $k_s(\nu)$ and $k_a(\nu)$, respectively (eqn [2]).

$$k_e(\nu) = k_s(\nu) + k_a(\nu) \quad [2]$$

Optical depth is a unitless measure of how much the radiation is reduced between two points, in this case from the TOA to an altitude z . The optical depth is equal to the integral of extinction over altitude (eqn [3]).

$$\tau_\nu(z) = \int_z^\infty \rho k_e(\nu) dz \quad [3]$$

Beer's law given in eqn [1] can be rewritten as eqn [4] using the definition of optical depth. Equation [4] shows that an increase in optical depth over some altitude interval is equal to the fractional reduction of intensity in that interval.

$$\frac{dI_d(\nu)}{I_d(\nu)} = -d\tau_\nu \quad [4]$$

The solution for the direct radiation at an altitude z is simply given by eqn [5], where $I_{d,0}(\nu)$ is the incident intensity of sunlight at the TOA.

$$I_d(\nu) = I_{d,0}(\nu) \exp[-\tau_\nu(z)] \quad [5]$$

The exponential term is the transmission, which for the direct beam is the fraction of incident radiation reaching a particular altitude. The transmission is always between 0 and 1.

When the optical depth at some altitude is much greater than unity, Beer's law shows that nearly all the direct beam is extinguished before reaching that altitude. When the optical depth is much less than unity, the direct radiation is reduced by a fractional amount almost equal to $1 - \tau_\nu(z)$. The solution of the radiative transfer equations to lowest order in $\tau_\nu(z)$ is known as the single-scattering approximation. For example, the global annual-mean aerosol optical depth is roughly 0.1 for the present-day atmosphere. Beer's law predicts that aerosol extinction reduces the direct beam at the surface to $\exp(-0.1)$ of its incident value. This reduction is nearly identical to the estimate from the single-scattering approximation, which

predicts that the direct beam is reduced to $1 - 0.1 = 90\%$ of its incident value.

Local optical depths vary considerably about the global annual-mean value. There are regions where the aerosol optical depth is frequently large enough to invalidate the single-scattering approximation. Nonetheless, the approximation is sufficiently accurate for calculating the global reflection, absorption, and transmission of solar radiation by aerosols. The estimates of these properties will apply to the entire atmosphere and solar spectrum, so for simplicity the explicit dependence on altitude and frequency will be omitted from the equations and results.

Changes in Reflection, Transmission, and Absorption

The amount of radiation extinguished from the direct beam is approximately $\tau_\nu I_{d,0}(\nu)$. Some of the extinguished radiation is absorbed in the atmosphere, and the remainder is converted to diffuse radiation. This diffuse radiation can be further scattered or absorbed in the atmosphere, although these effects are omitted in the single-scattering approximation. One of the main effects of aerosols on climate is in changing the amount of sunlight reflected back to space. The change in the planetary reflectivity, or albedo, from aerosols is due mostly to radiation being reflected out of the atmosphere; this reflected sunlight leaves the atmosphere as diffuse radiation. (Absorption of sunlight by aerosols such as soot also alters planetary albedo.)

The process of scattering sends diffuse radiation in all directions. The mathematical formalism for treating the subsequent propagation of diffuse radiation is relatively complex. However, the main effects of aerosols can be estimated using the two-stream approximation to radiative transfer. In this simplification, all the radiation propagating downward toward the surface is combined in a single downward flux of energy, or 'stream.' This stream includes the direct beam and any diffuse radiation scattered toward the Earth's surface. The downward stream is represented by the symbol $F^\downarrow$. All the diffuse radiation propagating upward is combined into the upwelling stream denoted by $F^\uparrow$. The fluxes are in units of energy per unit area per unit time and are conventionally expressed in watts per square meter (W m^{-2}). For example, the global annual-mean solar flux incident upon the TOA is $F_0^\downarrow = 342 \text{ W m}^{-2}$.

If the optical depth τ of the aerosols is small and if the radiation reflected by the surface is negligible, the upwelling stream is given by eqn [6].

$$F^\uparrow = \omega b \tau F_0^\downarrow \quad [6]$$

The factor ω is the ratio of scattering to total extinction and is known as the single-scattering albedo. The single-scattering albedo is the fraction of incident energy scattered each time sunlight interacts with an aerosol particle. In the two-stream approximation, the factor b , known as the backscattering ratio, is the fraction of scattered energy that is reflected upward. For typical aerosols, b is roughly 0.3. The single-scattering albedo determines the total amount of radiation that is scattered in interactions with aerosols, and the backscattering ratio determines how much of the scattered radiation is directed toward space.

For example, if $\varpi = 0.95$, then 95% of sunlight is scattered and only 5% is absorbed. If $\varpi = 1$, no energy is removed from the sunlight by absorption, and the aerosol is called a conservative scatterer. For sulfate and sea-salt aerosols, $\varpi \approx 1$ for visible light. However, ϖ can be 0.3 or lower in visible wavelengths for black carbonaceous aerosols generated by combustion. Aerosols with $\varpi < 0.9$ in visible frequencies are considered to be quite absorptive.

From eqn [2], ϖ can be written in terms of the specific extinctions as eqn [7].

$$\varpi = \frac{k_s}{k_e} \quad [7]$$

The fractional absorption in each interaction of sunlight with aerosols is known as the coalbedo and is given by $1 - \varpi$. Even if the coalbedo is very close to 0 for a single interaction, the amount of absorption *accumulates* each time a beam of light interacts with aerosols. The radiant energy is reduced by a factor of $1 - \varpi$ after each interaction. After N interactions, the energy remaining is proportional to ϖ^N . In the single-scattering approximation, only one interaction is considered. Therefore, the total amount of energy absorbed is proportional to the coalbedo (eqn [13]).

The change in the planetary albedo ΔR from aerosols is the ratio of the upwelling reflected radiation $F^\uparrow$ to the incident radiation $F_0^\downarrow$ (eqn [8]).

$$\Delta R = \frac{F^\uparrow}{F_0^\downarrow} = \varpi b \tau \quad [8]$$

To provide a realistic estimate of the change in planetary albedo, the extinction by the rest of the atmosphere should be included in the calculation. The change in albedo is estimated using $\Delta R_a = f_a \Delta R$. The empirical factor f_a is approximately equal to 0.2 and includes the effects of atmospheric gases, water vapor, and clouds. For a nonabsorbing aerosol with $\varpi \approx 1$, $b = 0.3$, and $\tau \approx 0.1$, $\Delta R_a \approx 0.0006$. Since the global planetary albedo is approximately 0.3, the aerosols increase the planetary albedo by roughly 2% in relative terms. The corresponding increase in upwelling flux is approximately 2 W m^{-2} .

If the optical depth τ of the aerosols is small and if the radiation reflected by the surface is negligible, the downwelling stream at the Earth's surface is given by eqn [9].

$$F^\downarrow = (1 - \tau)F_0^\downarrow + (1 - b)\varpi\tau F_0^\downarrow \quad [9]$$

Aerosols have two effects on the downwelling solar radiation at the surface corresponding to the terms on the right-hand side of eqn [9]. The effects have opposite sign and therefore partially offset one another. The first effect is the reduction of the direct beam by scattering and absorption. The second effect is the addition of diffuse radiation that represents sunlight scattered from the direct beam toward the surface. Since b is the fraction of radiation scattered upward, $1 - b$ is the fraction of radiation scattered downward. The reduction is equal to $-\tau F_0^\downarrow$ and the addition is equal to $(1 - b)\varpi\tau F_0^\downarrow$. The ratio of the diffuse flux addition and direct-beam flux reduction is as given by eqn [10], which shows that the increase in diffuse flux is always less than the reduction in direct flux.

$$0 \leq (1 - b)\varpi \leq 1 \quad [10]$$

Therefore, the net effect of aerosols is to reduce the total amount of sunlight reaching the Earth's surface. The change in transmission is the ratio of the change in the downwelling flux to the flux incident on the TOA. The expression for the change in transmission is given by eqn [11].

$$\Delta T = \frac{F^\downarrow - F_0^\downarrow}{F_0^\downarrow} = (1 - b)\varpi\tau - \tau \quad [11]$$

The amount of sunlight absorbed by aerosols can be derived using the principle of conservation of energy, which states that the energy in a closed system is constant. The atmosphere is an example of an open system since it can exchange energy and material with the surface and with space. However, the combination of the atmosphere, the fluxes to the surface, and the fluxes to space comprises a closed system. In this system, the albedo determines the flux to space, the transmission determines the flux to the surface, and the absorption determines the conversion of light to internal energy within the atmosphere. The solar energy incident on the atmosphere does not change when aerosols are present. Therefore, the sum of changes in the albedo, transmission, and absorption must equal 0 (eqn [12]).

$$\Delta A + \Delta R + \Delta T = 0 \quad [12]$$

This condition can be solved for the absorption ΔA as in eqn [13].

$$\Delta A = -(\Delta R + \Delta T) = (1 - \varpi)\tau \quad [13]$$

Effects of Surface Reflection

When an aerosol layer is present above a nonreflective surface, it always increases the atmospheric albedo. As eqn [8] shows, ΔR is positive regardless of the optical properties of the aerosol. The surface reflectivity R_s is the fraction of radiation incident on the surface that is reflected back into the atmosphere. Under overhead Sun, the ocean may be treated as a nonreflective surface because the reflectivity is just 3%. However, there are surface types that reflect at least 50% of the incident sunlight, for example, sea ice, glaciers, snow, and some desert areas. The effects of surface reflectivity can easily be calculated using the two-stream and single-scattering approximations.

When the effects of surface reflectivity are included, the albedo ΔR computed in eqn [8] assuming $R_s = 0$ must be corrected in the following three ways:

1. Incoming radiation interacts with the aerosol as it propagates toward the surface. A fraction $1 + \Delta T$ is transmitted to the surface, and some of it is reflected back to space.
2. Radiation reflected from the surface interacts with the aerosol as it propagates toward space. A fraction $1 + \Delta T$ is transmitted to space.
3. Radiation reflected from the surface interacts with the aerosol as it propagates toward space. A fraction ΔR is reflected back to the surface, where some of it is reflected upward and is transmitted to space.

These effects are illustrated in Figure 1.

Figure 1 Interactions between incident sunlight, an aerosol layer, and a reflective surface. The incident solar flux is $F_0^{\downarrow} = 1$. The albedo and transmission of the layer are ΔR and ΔT , respectively, and the reflectivity of the surface is R_s . Solid black arrows point along the direction of the sunlight, and dashes indicate where the sunlight is attenuated by the aerosol layer.

In mathematical form, the change $\Delta R'$ in planetary albedo for aerosols above a reflective surface is given by eqn [14].

$$\Delta R' - \Delta R = (\Delta T)R_s + R_s(\Delta T) + R_s(\Delta R)R_s \quad [14]$$

The three terms on the right-hand side of eqn [14] correspond to the three effects discussed above. $\Delta R'$ can be simplified using the conservation of energy (eqn [12]) to rewrite ΔT in terms of ΔA and ΔR . After some algebraic manipulation, the resulting expression for the albedo is as given by eqn [15].

$$\Delta R' = (1 - R_s)^2 \Delta R - 2R_s \Delta A \quad [15]$$

It is easy to show that $\Delta R' < \Delta R$ whenever $R_s > 0$. This inequality states that surface reflectivity always reduces the effects of aerosols on the planetary albedo. There are two mechanisms for the reduction, corresponding to the two terms on the right-hand side of eqn [15]. First, when most of the sunlight incident on the surface is reflected, the sunlight reflected by aerosols is a relatively small component of the upwelling flux. If the surface is completely reflective, all solar radiation incident on the atmosphere is either scattered back to space or absorbed in the atmosphere. Additional scattering by aerosols cannot increase the diffuse radiation emitted to space. Therefore, $\Delta R' \leq 0$ when $R_s = 1$. Second, multiple scattering of diffuse radiation between the aerosol and the surface increases the fraction of incident radiation that is absorbed. Because energy is conserved, the absorption reduces the amount of sunlight that can be reflected to space.

Under certain conditions, the presence of aerosols will either reduce the planetary albedo or leave it unchanged. If the albedo is reduced, then conservation of energy requires that the absorption within the combined surface-atmosphere system must increase. More absorption results in greater internal energy, or heat, within the Earth's atmosphere or surface. Consequently, when $\Delta R' \leq 0$ there is additional heating within the Earth-atmosphere system. The conditions for heating follow from substitution of ΔR and ΔA (eqns [8] and [13]) into the inequality $\Delta R' \leq 0$. The criterion, which was first discovered by Chylek and Coakley, is given as [16].

$$\frac{(1 - \varpi)}{\varpi b} \geq \frac{(1 - R_s)^2}{2R_s} \quad [16]$$

This condition is independent of the total aerosol optical depth (or mass) present in the atmosphere. It depends only upon intrinsic optical properties of the aerosol. Regardless of the value of R_s , the condition can always be satisfied with sufficiently small values of either the backscatter fraction b or the single-scattering albedo ϖ . Assuming $R_s \cong 0.12$, for aerosols with a typical value of $b = 0.3$, the criterion indicates that aerosols heat the climate system if $\varpi \leq 0.51$. Since measured values of ϖ often do not fall below 0.8, $\Delta R' > 0$. (An exception is soot aerosol, which is sometimes observed with lower ϖ .) Thus, aerosols cool the global climate system by reflecting sunlight back to space before it can be absorbed. Over regions with persistent ice or snow cover at high latitudes, however, R_s can easily exceed 0.5. When $R_s \cong 0.5$, the criterion for heating is $\varpi \leq 0.93$. Carbonaceous particles released by combustion frequently satisfy this condition on single-scattering albedo. Polar regions are therefore susceptible to heating when aerosols are only moderately absorptive.

Interactions with Thermal Radiation

Aerosols interact with thermal infrared radiation from Earth's surface and atmosphere, and aerosols can emit additional thermal radiation. For aerosols near the Earth's surface, the effects on thermal radiation are generally much less significant than the effects on solar radiation. However, the thermal effects of thick dust plumes and stratospheric aerosols are sufficiently large to register on satellite instruments.

At infrared frequencies, the extinction by aerosols is mostly due to absorption. To a reasonable approximation, scattering may be omitted from calculations of infrared fluxes. In addition, the atmosphere and surface both act as sources of thermal radiation. The flux of infrared radiation from the Sun is actually much smaller than these terrestrial sources and can be neglected in most applications.

The Stefan-Boltzmann law states that the thermal flux from a perfect thermal source at temperature T is σT^4 . The constant σ is the Stefan-Boltzmann constant and is approximately equal to $5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$. A perfect thermal source, or 'black body,' is an optical medium that absorbs all thermal radiation incident upon it. Aerosol layers are rarely thick enough to qualify as perfect thermal sources. Instead, the aerosols may be treated as 'gray bodies' that emit a thermal flux equal to $\varepsilon \sigma T^4$. The factor ε is known as the emissivity, and is a unitless number between 0 and 1. The closer ε is to 1, the more the gray body resembles a perfect thermal source.

Suppose the gray body is surrounded by a perfect thermal medium at the same temperature T . From the laws of thermodynamics, the gray body will be in thermal equilibrium with the surrounding medium. In equilibrium, the internal energy of the gray body is constant. Since the gray body is emitting a flux of thermal energy equal to $\varepsilon \sigma T^4$, it must also absorb energy at the same rate. The flux incident on the gray body from the medium is σT^4 and a fraction ΔA of this flux is absorbed. Because thermal equilibrium requires that the absorbed and emitted fluxes are equal, $\Delta A = \varepsilon$. The transmission can be derived from the conservation of energy (eqn [12]). If the gray body does not

reflect thermal radiation and $\Delta R \cong 0$, then the transmission is given by eqn [17].

$$\Delta T \cong -\Delta A = -\epsilon \quad [17]$$

To simplify the analysis, various components of the atmosphere may also be treated as gray bodies. The emissivity of the stratosphere will be denoted by ϵ_* .

The thermal effects of aerosols in the stratosphere and near the surface are illustrated in Figures 2 and 3. Stratospheric aerosols are often created by volcanic eruptions, and aerosols near the surface result from natural and anthropogenic processes. The infrared fluxes can be analyzed with the same two-stream techniques applicable to solar radiation. Let $F_t^\uparrow$ represent the upwelling flux from the troposphere incident on the bottom of the stratospheric aerosol layer. Let $F_a^\downarrow$ represent the downwelling flux from the atmosphere above the surface aerosol layer incident on the top of the layer. The temperature and emissivity of the stratospheric aerosol are T_v and ϵ_v , and the temperature and emissivity of the surface aerosol are T_s and ϵ_s respectively.

The change in the upwelling flux at the TOA has two components. The first represents the reduction in $F_t^\uparrow$ by partial transmission through the aerosol layer. The second represents the additional thermal emission from the aerosol layer. The total change in upwelling flux is given by eqn [18].

Figure 2 Interactions of thermal infrared radiation with an aerosol layer adjacent to the stratosphere. The temperature and emissivity of the aerosol layer are T_v and ϵ_v , respectively, and the emissivity of the stratosphere is ϵ_* . The upwelling infrared flux from the troposphere incident upon the bottom of the aerosol layer is $F_t^\uparrow$. Arrows point along the direction of the radiation, and dashes indicate where the radiation is attenuated by the aerosol layer and the stratosphere.

Figure 3 Interactions of thermal infrared radiation with an aerosol layer adjacent to the surface. The temperature and emissivity of the aerosol layer are T_s and ϵ_s , respectively. The downwelling infrared flux from the atmosphere incident upon the top of the aerosol layer is $F_a^\downarrow$. Arrows point along the direction of the radiation, and dashes indicate where the radiation is attenuated by the aerosol layer.

$$\Delta F_v^\uparrow = \epsilon_v (\sigma T_v^4 - F_t^\uparrow) (1 - \epsilon_*) \quad [18]$$

A similar analysis of the surface aerosol layer shows that the change in downwelling thermal flux is as given by eqn [19].

$$\Delta F_s^\downarrow = \epsilon_s (\sigma T_s^4 - F_a^\downarrow) \quad [19]$$

Reasonable values for the aerosol parameters for aerosols located in the tropics are given in eqn [20].

$$\begin{aligned} T_v &= 195 \text{ K} & \epsilon_v &= 0.005 \\ T_s &= 295 \text{ K} & \epsilon_s &= 0.05 \end{aligned} \quad [20]$$

For the purposes of illustration, the unperturbed atmospheric parameters are given in eqn [21].

$$\begin{aligned} \epsilon_* &= 0.088 \\ F_t^\uparrow &= 240 \text{ W m}^{-2} \\ F_a^\downarrow &= 380 \text{ W m}^{-2} \end{aligned} \quad [21]$$

The resulting changes in the upwelling and downwelling thermal infrared fluxes are given in eqn [22].

$$\begin{aligned} \Delta F_v^\uparrow &= -0.7 \text{ W m}^{-2} \\ \Delta F_s^\downarrow &= 2.5 \text{ W m}^{-2} \end{aligned} \quad [22]$$

In this illustrative calculation, aerosols in the stratosphere decrease the outgoing infrared flux, while aerosols near the surface increase the downwelling infrared flux. In more realistic calculations, the thermal infrared flux at the TOA will generally decrease and the flux at the bottom will generally increase. The basic reason is that the global infrared flux emitted to space is equal to the radiation from a perfect thermal source at temperature $T = 255.5 \text{ K}$. This atmospheric radiation is not in equilibrium with aerosol layers at temperatures different from T . The absence of equilibrium means that the colder stratospheric aerosols will absorb some of the upwelling atmospheric flux, thereby reducing the flux emitted to space. Similarly, the warmer stratospheric aerosols emit more radiation to the surface than the atmosphere alone.

Global Quantification of Aerosol–Radiation Interactions

As has been presented, interactions of atmospheric aerosols and radiation can be described by aerosol optical depth τ , single-scattering albedo ω , backscattering fraction b , and the reflectivity of the Earth surface R_s . These properties can be globally quantified using sensors on satellites. The sensors are designed to measure radiation reflected and emitted by the atmosphere and Earth surface in discrete narrow wavelength bands. With knowledge of how the Earth surface and atmosphere reflects, absorbs, and emits radiation in these narrow bands, properties of the Earth system can be derived (see **Satellites and Satellite Remote Sensing: Aerosol Measurements; Research**). The last decade has seen major advances in satellite technologies including the deployment of instruments specifically intended to measure aerosol properties. The future promises additional advances to improve global characterization of atmospheric aerosols and associated climate effects.

Aerosol Optical Depth

Total column optical depth τ is the most routinely globally retrieved aerosol quantity. Regions with high aerosol optical depths have strong aerosol–radiation interactions. Aerosol optical depth is currently being measured by multiple satellite sensors. As an example, [Figure 4\(a\)](#) shows τ from the moderate resolution imaging spectroradiometer (MODIS) on board NASA's Terra satellite. Though MODIS measures τ for all aerosol types, additional processing was performed such that this figure shows τ for only a portion of the fine-mode aerosols, mainly smoke and pollution particles. In general, these

aerosols are primarily carbonaceous (black and organic carbon) and sulfur-containing species. Larger particles that are often naturally produced such as dust and sea salt are not included in this figure. Plumes with high aerosol optical depth can be observed in industrialized regions with heavy fossil fuel combustion (e.g., North America, Europe, and Eastern Asia) and areas with biomass burning (e.g., Central Africa, eastern Siberia, western and northern United States, and Canada). The plumes disperse over land and ocean regions following circulation patterns, ultimately dying off via transformation and removal processes downwind of the sources. The global mean

Figure 4 Distributions of (a) aerosol optical depth at 0.55 μm and (b) shortwave direct radiative forcing (DRF) from a portion of fine-mode aerosols. Distributions are derived from MODIS collection 5 and represent annual means for 2002. White indicates areas without data. Reprinted from Bellouin, N., Jones, A., Haywood, J., Christopher, S., 2008. Updated estimate of aerosol direct radiative forcing from satellite observations and comparison against the Hadley Centre climate model. *Journal of Geophysical Research* 113. <http://dx.doi.org/10.1029/2007JD009385>.

optical depth τ shown in Figure 4(a) is 0.043. Optical depth is 0.021 and 0.107 over ocean and land regions, respectively.

Though MODIS can retrieve aerosol optical depth at most locations around the globe, the presence of clouds and/or highly reflective surfaces (e.g., ice or desert sand) precludes its calculation (see, e.g., the lack of AOD values in Northern Africa in Figure 4). This is because the contribution to total upwelling radiation from these highly reflective surfaces can far outweigh the contribution from the atmospheric aerosol. However, other satellite instruments such as ozone monitoring instrument (OMI), multiangle imaging spectroradiometer (MISR), and polarization and directionality of Earth's reflectances (POLDER) are capable of retrieving aerosol optical depth above somewhat higher reflectance backgrounds. OMI does this by measuring aerosol absorption in the ultraviolet (UV); scattering of UV light is highly efficient by molecules in the atmosphere and thus minimal UV reaches the surface. (Moreover, most surfaces on Earth are dark in the UV.) Since minimal UV radiation reaches the surface of Earth, aerosol optical depth as measured by OMI is less sensitive to aerosols at lower altitudes than higher altitudes. MISR works by observing the Earth system simultaneously at nine different viewing angles and four wavelengths ranging from the blue to near-infrared. POLDER separates reflected light from the atmosphere and the surface by measuring its polarization at multiple angles.

Direct Radiative Forcing

Ultimately we are interested in diagnosing how aerosol–radiation interactions affect Earth's climate. Since aerosols reflect sunlight and thus partially offset warming from greenhouse gases, accurately quantifying aerosol–radiation interactions is critical to understanding anthropogenic global climate change. Direct radiative forcing (DRF) is a frequently used metric to describe the change in net radiation at the TOA caused by scattering and absorbing aerosols. Aerosol-induced changes

in clouds that indirectly alter net radiation are not included in DRF but are discussed in Aerosols: Aerosol–Cloud Interactions and Their Radiative Forcing.

Various methods are used to calculate DRF using satellite products, most of which require some modeling. For example, with knowledge of the global distribution of τ from aerosols (Figure 4(a)), DRF can be derived using radiative transfer modeling. Figure 4(b) shows such an estimate of shortwave DRF. Other than τ , the radiative transfer model takes as inputs the aerosol optical properties already discussed, the aerosol vertical profile, and the surface albedo. However, until recently the aerosol optical properties and vertical profiles have not been measured at global scale. Thus, aerosol optical properties have often been derived with surface measurements using sun-photometers, assuming that the measurements at these point locations are representative of wider areas. (See the next section on recent advances for globally measuring τ with satellites.) Further, while the vertical profile of aerosols is an important input to the radiative transfer model, the lack of global measurements has generally required the use of simplified assumptions. (See the next section on recent advances in measuring aerosol vertical profiles with satellites.) Lastly, the surface albedo can be globally quantified using satellite sensors such as MODIS (Figure 5).

It can be observed in Figure 4(b) that DRF is highest in areas with high values of τ (Figure 4(a)). The global mean shortwave DRF shown in this figure is -1.30 W m^{-2} , while values over ocean and land are -0.60 and -3.27 W m^{-2} , respectively. Note that shortwave DRF does not include changes in thermal (longwave) radiation. Changes in thermal radiation are expected to be small for the fine-mode but may be of importance for larger naturally produced aerosols (Section Longwave Forcing). To get a sense of the magnitude of the aerosol DRF, the increase in atmospheric abundance of greenhouse gases from preindustrial times to the year 2005 caused a radiative forcing of approximately 2.9 W m^{-2} .

Figure 5 Albedo of the land surface during April 2002 derived using MODIS. White indicates regions without available data. Albedo of the ocean is not shown but is generally low (<0.1). Quantifying aerosol optical depth using satellites is more challenging over areas with high surface albedo (shown in red) such as deserts and snow/ice covered parts of Earth. Original image by Crystal Schaaf. <http://earthobservatory.nasa.gov>.

New Frontiers in Global Measurements of Aerosols

As discussed in the previous section, accurately quantifying DRF using radiative transfer models requires accurate estimates of the global distribution of aerosol optical properties and vertical profiles. Until recently these estimates have been mostly based on point measurements or assumed. While point measurements can be very accurate, they are not always representative of global distributions. Recent advances in satellites are making such measurements possible.

Single-Scattering Albedo

Recall that ω conveys the relative amount of scattering vs absorption of radiation by a particle. Aerosols with low ω like soot can reduce sunlight at the Earth surface but also heat Earth's atmosphere, leading to changes in the hydrological cycle in areas with heavy loading. Single-scattering albedo is currently being measured by both OMI and MISR. The OMI, which is on board NASA's AURA satellite, has been retrieving single-scattering albedo since 2005. **Figure 6** shows annual mean ω for 2007. Note that this figure includes ω from both fine-mode and larger aerosols. Single-scattering albedo is generally high (>0.86) and thus solar radiation is mostly scattered rather than absorbed by aerosols around the globe. Regions with increased carbonaceous aerosol from combustion have lower ω than remote ocean regions containing mostly sea-salt aerosol. Regions with high dust loading (e.g., Northern Africa) also show relatively lower ω . It should be noted that retrievals of single-scattering albedo have relatively high uncertainty. For OMI, the high uncertainties stem in part from assumptions that are required about the vertical profile of

aerosol. Additionally, results are derived using only UV radiation even though ω is a wavelength-dependent property, and for radiative forcing, its value in the visible part of the spectrum is most important. New methods are being used to estimate single-scattering albedo in the visible using OMI.

The future may bring new techniques for quantifying ω . One possibility is the use of hyperspectral satellites. Historically, most satellite sensors have measured at most tens of spectral bands. But new hyperspectral sensors have thousands of channels, improving the fidelity at which the atmosphere can be characterized. Additionally, new algorithms for existing satellite sensors are continually being developed. For example, an algorithm has been proposed to derive ω based on sun glint, which is a phenomenon that occurs when the satellite sensor captures mirrorlike reflection of sunlight off the ocean. Sun glint portions of satellite images can sometimes reveal atmospheric properties that are not ordinarily retrievable. In this case, sun glint regions are used as a background for viewing aerosol absorption properties. Though attempts are being made to use this method with existing satellites such as MODIS, a satellite designed to continually observe glint regions would provide better sampling statistics. As a second example, a new algorithm is currently in development for OMI that allows for characterizing ω (and τ) above clouds.

Aerosol Vertical Profiles

Global characterization of aerosol vertical profiles is one of the most significant recent advances in remote sensing of particles. Knowledge of the vertical profile of particles is important in determining its influence on radiation, but also its atmospheric lifetime. Both are closely related to the vertical position of the

Figure 6 Single-scattering albedo ω derived using the UV channel of the ozone monitoring instrument (OMI), which was launched in 2005. This is the annual mean for 2007. Figure courtesy Omar Torres.

aerosol relative to clouds. Aerosols below clouds will experience lower incident radiation and are more likely to rain out via wet deposition. Aerosols above clouds will experience higher incident radiation (i.e., both downwelling radiation from the sun and upwelling radiation that has been reflected by the clouds below) and will have longer lifetimes due to the lack of rainfall from above. Aerosols with low τ that are positioned above clouds can absorb a significant amount of radiation and thus warm the surrounding air.

The cloud-aerosol lidar and infrared pathfinder satellite observation (CALIPSO) satellite, launched in 2006, is providing new insight into aerosol layer thickness, composition, and altitude. This satellite contains the first 'active' light detection and ranging (LIDAR) in space that is optimized to characterize aerosols (and clouds). LIDAR is similar to radio detection and ranging (RADAR) but uses shorter wavelength energy from laser beams rather than radio energy. Given the active nature of LIDAR, CALIPSO can characterize both the sunlit and dark parts of Earth. (Passive sensors that measure reflected shortwave radiation from the sun cannot characterize the atmosphere at night.) Vertically resolved measurements from CALIPSO can now be used for characterization of Earth's atmosphere, comparison to global climate models, and as inputs to calculations of climate relevant metrics such as shortwave DRF.

An example of an aerosol vertical profile measured by CALIPSO is shown in Figure 7. The red line in the inset of the

figure shows that the location of the transect is off the west coast of Africa where biomass burning aerosols are frequently encountered. The color scale of the vertical profile represents the intensity of light (532 nm) from the LIDAR that was backscattered. The blue and purple colors indicate minor backscattering from air molecules in the clean atmosphere, the light green colors indicate moderate scattering by an elevated layer of biomass burning aerosol, and the red colors indicate heavy backscattering by a layer of marine clouds, which are frequently observed in this area. Backscattering values underneath the cloud are not always reliable because the LIDAR signal cannot fully penetrate the optically thick cloud.

Longwave Forcing

In general DRF includes changes in TOA radiation caused by altering both shortwave and thermal (longwave) radiation. We are often concerned only with DRF from anthropogenic aerosol, which in most cases has negligible longwave DRF. Interactions of aerosols with thermal radiation are significant only for particles with diameter similar in magnitude to wavelengths in the thermal region of the electromagnetic spectrum; generally only naturally occurring aerosols such as dust and sea-salt have sufficiently large diameter. Also, these large diameter aerosols can have a more significant effect on the thermal energy budget of Earth when at high altitudes vs low altitudes. This is because high altitude aerosols are cold. Thus, the

Figure 7 Vertical profile of backscatter signal ($\text{st}^{-1} \text{km}^{-1}$) at 532 nm from the CALIPSO LIDAR (named CALIOP) for 9 July 2009. The red line in the inset figure shows the location of the transect off the west coast of Africa. The black line shows ground level and the yellow line shows the height of the boundary layer (from another data source). On the vertical profile, blue colors are associated with weak backscattering by molecules in the clean upper atmosphere, light green colors show moderate backscattering by an elevated aerosol layer presumably from biomass burning, and red colors show strong backscattering by a layer of marine clouds. Analysis of aerosol–cloud interaction from multi-sensor satellite observations. *Geophysical Research Letters* 37. <http://dx.doi.org/10.1029/2009GL041828>.

thermal radiation absorbed by the high altitude aerosol is reemitted at cold temperatures. Consequently the thermal energy that escapes to space is reduced, leading to an increase in the energy absorbed by the Earth system. Dust storms are capable of lifting large diameter dust particles to high altitudes. Recent research has shown that longwave DRF from dust storms can be comparable in magnitude to greenhouse gas forcing in certain regions. The vertical fidelity of CALIPSO sensors allow for effects of natural aerosols on thermal radiation (i.e., longwave DRF) to be better characterized.

Conclusions

Accurately quantifying aerosol forcing globally is one of the most challenging aspects of evaluating past climate and predicting future climate. While detailed monitoring of aerosols has occurred in certain regions (largely for characterizing air pollution), we are just beginning to have a more detailed understanding of aerosols globally. This global quantification has been one of our biggest challenges and is a key for both quantifying aerosol–radiation interactions and evaluating global models. The future holds new scientific challenges to be solved related to reducing uncertainties in global measurements of aerosol properties. A further practical challenge for the future is to ensure that the satellites that make global characterization of aerosols possible are sustained. Ultimately, our ability to characterize aerosol–radiation interactions, and consequently climate effects of aerosols, will hinge on our ability to globally characterize the properties discussed in this article.

Synopsis

The atmospheric aerosols emitted by human activities interact with radiation, clouds, and snow-covered surfaces, thus exerting a perturbation of the Earth's energy budget called radiative forcing (RF). Aerosol RF is strongly variable in time and space, but the net global effect is to offset the positive RF by long-lived greenhouse gases and counteract the associated global warming. In turn, changes in temperature and precipitation affect aerosols, giving rise to feedbacks that strengthen or oppose the initial climate change. Finally, aerosols can be used as climate engineering tools in efforts to mitigate climate change.

Introduction

Aerosols, the liquid and solid particles in suspension in the atmosphere, matter to the scientific study of climate change for three reasons. First, they are optically active species, interacting with solar and terrestrial radiation directly by scattering and absorption, and indirectly by modifying the microphysical properties of clouds and the radiative properties of surfaces covered by snow and ice. Perturbations to atmospheric distributions of aerosols therefore translate into perturbations of the Earth's radiative budget, which can enhance or counteract the radiative perturbations exerted by changes in the concentrations of long-lived greenhouse gases such as carbon dioxide and methane.

Second, human activities have profoundly perturbed aerosol distributions. Since the start of the Industrial Revolution in the eighteenth century, road transport, aviation, maritime shipping, industries, power plants, domestic cooking stoves, and forest-clearing fires have all emitted aerosols and their gaseous precursors, increasing the amount of particles in the atmosphere and modifying their chemical composition. Figure 1(a) shows a time series of globally averaged emissions of the main anthropogenic aerosol and precursor species since the year 1850. According to those estimates, anthropogenic emissions of sulfur dioxide, the gaseous precursor to sulfate aerosols, have

risen from a global total of 2 Tg for the year 1850 to more than 120 Tg per year at the end of the twentieth century. Over the same period, primary emissions of carbonaceous aerosols from fossil fuel combustion, and emissions of ammonia, the precursor of nitrate aerosols, increased by a factor 3. Increases in emissions increase aerosol mass over the source region and transport pathways, as illustrated by Figure 1(b), which shows changes in surface concentrations of sulfate aerosols over the industrial period. Increases do not cover the whole globe because strong sinks, dominated by washout by precipitation, prevent aerosols from accumulating in the atmosphere. The very heterogeneous distribution of aerosol concentrations and compositions in the atmosphere complicates the study of their climatic role compared to that of well-mixed and long-lived greenhouse gases such as carbon dioxide.

The third and last reason why aerosols play an important role in climate change is the dependence of their sources and sinks on the state of the climate. As climate responds to an initial radiative perturbation, the distributions of natural and anthropogenic aerosols and their gaseous precursors change, giving rise to radiative feedbacks that either oppose or reinforce the initial radiative perturbation. The Introduction section of this article introduces the three important concepts of radiative forcing (RF), fast adjustments, and climate response, which are relevant to the multiple roles of aerosols in climate change. Section

Figure 1 (a) Left panel: Time series of global, annual anthropogenic emissions of sulfur dioxide, ammonia, and primary carbonaceous aerosols over the period 1850–2000 according to the CMIP5 data set. (b) Right panel: Modeled changes in column-integrated concentrations of sulfate aerosols, in mg[S] m^{-2} , due to changes in anthropogenic emissions of sulfur dioxide over the period 1850–2000.

Instantaneous and Effective RF, and Climate Response then reviews the mechanisms through which aerosols perturb the Earth's RF, while Section Mechanisms of Aerosol RF discusses how aerosols are in turn influenced by climate change. Finally, the proposed use of aerosols as tools for climate mitigation is discussed in Section Climate Response and Aerosol Feedbacks.

Instantaneous and Effective RF, and Climate Response

RF quantifies, in units of W m^{-2} , the change in the energy available to the climate system caused by a change in one or more components of the Earth's radiative budget. The concept of RF finds its usefulness from climate modeling studies that found that the long-term change in globally averaged surface temperature is proportional, within 20%, to the RF initially applied. More formally, RF is defined as the instantaneous perturbation in net radiative flux at the tropopause exerted by a change in a component of the radiative budget, with surface temperature and tropospheric state maintained in their unperturbed state (Figure 2). By convention, negative RFs denote a decrease in net radiative flux, or a loss of energy from the climate system. Conversely, positive RFs denote a gain of energy to the climate system. In climate research, RF is typically defined with respect to the year 1750, taken as representative of unperturbed conditions because that year predates the Industrial Revolution. It should be noted however that in terms of aerosols, the year 1750 already experienced anthropogenic perturbations from the stoves used in domestic cooking and the forest and field clearing fires that were common agriculture practices at the time. Those emissions are however taken as being part of the preindustrial (PI) climate system.

Figure 2 Diagram showing the relationship between radiative perturbation, noted ΔF , and change in globally averaged surface temperature, noted ΔT , to illustrate the concepts of instantaneous RF, effective radiative forcing (ERF), and climate response. Instantaneous RF is the initial radiative imbalance, chosen here positive, with respect to a reference state, typically PI conditions. ERF is the sum of RF and the subsequent fast atmospheric adjustments that do not affect globally averaged surface temperature. The climate system then returns to the reference state (PI) through a change in globally averaged surface temperature. To a good approximation, the surface temperature change is proportional to the ERF, with the constant of proportionality called climate sensitivity. The new surface temperature at equilibrium is called climate response at equilibrium.

The climate system results from the coupling of the atmosphere and the ocean. Because the ocean represents 90% of the heat capacity of the climate system, its response to an instantaneous RF is much slower, on the order of decades, than that of the atmosphere, which adjusts within weeks. It is therefore useful to distinguish two timescales in the response to a RF: fast adjustments and a slow climate response. Fast adjustments (Figure 2) directly depend on the RF and operate on atmospheric timescales, affecting the vertical distribution of temperature and moisture, thus the formation of clouds. ERF is the sum of RF and its fast adjustments. ERF is weaker than RF when fast adjustments counteract the initial forcing, as represented in Figure 2. Conversely, ERF is stronger than RF when fast adjustments enhance the initial forcing. Fast adjustments are particularly important for carbonaceous aerosols, and ERF is then a better predictor of the subsequent long-term change in surface temperature than instantaneous RF. The slow climate response (Figure 2) depends on changes in globally averaged surface temperatures and therefore operates on oceanic timescales. To return to radiative balance, the globally averaged surface temperature increases if the ERF is positive or decreases if the ERF is negative. This change of temperature is determined by the sensitivity of the climate system, which is a property of the atmosphere–ocean system and is, to a good first approximation, independent of the RF mechanism.

Mechanisms of Aerosol RF

Anthropogenic aerosols exert a RF through three mechanisms, represented schematically in Figure 3: aerosol–radiation interactions, aerosol–cloud interactions, and aerosol–surface interactions. Those three categories were introduced by the Fifth Assessment Report of the Intergovernmental Panel on Climate Change to unify the terminology of aerosol RF.

Aerosol–Radiation Interactions

The radiative forcing due to aerosol–radiation interactions (RFari), also termed aerosol direct RF in the scientific literature, stems from the additional scattering and absorption of radiation that follows the increase in aerosol mass provided by anthropogenic emissions of aerosols and gaseous precursors (Figure 3(a)). Anthropogenic aerosols originate in majority from gas-to-particle conversion processes and from primary emissions during combustion of fossil fuels or biomass. They are therefore mostly composed of particles with sizes smaller than $1 \mu\text{m}$ and consequently interact more effectively with wavelengths in the solar spectrum, with much weaker influences on terrestrial radiation. RFari depends on the horizontal and vertical distributions of aerosol concentrations and scattering and absorption properties, which in turn depend on aerosol sizes and chemical composition. Environmental factors, such as the solar zenith angle, and the reflectance of the surface or cloud underlying the aerosol layer, also play important roles. One crucial aspect of RFari is that it can be either negative or positive at the top of atmosphere: its sign depends on the competition between aerosol scattering and absorption processes, which is affected by the reflectance of the surface below the aerosol layer. For a given aerosol size, the

Figure 3 Mechanisms of aerosol RF and fast adjustments. (a) Compared to a natural atmosphere, anthropogenic aerosols (brown circles) scatter and absorb additional solar radiation (orange arrows), reflecting energy back to space or absorbing it in this atmosphere, cooling the surface locally, and warming the aerosol layer for absorption aerosols. The new vertical temperature gradient then affects atmospheric stability and cloud formation. (b) Compared to a natural atmosphere, anthropogenic aerosols provide additional cloud condensation nuclei, leading to the formation of more, smaller cloud droplets. More droplets reflect more solar radiation back to space. Smaller droplets may not easily form large raindrops, potentially decreasing precipitation and increasing cloud lifetime. (c) Deposition of anthropogenic aerosols onto ice and snow surfaces decreases their albedo.

likelihood of a positive top-of-atmosphere RFari increases with aerosol absorption and reflectivity of the surface. A purely scattering anthropogenic aerosol, such as sulfate, exerts a negative RFari over most regions. The more absorbing carbonaceous aerosols exert a negative RFari over dark surfaces, such as vegetated and oceanic surfaces, and a positive RFari over brighter surfaces, such as deserts and icy regions. This point is well illustrated by the satellite imagery shown in **Figure 4**, where a plume of moderately absorbing carbonaceous aerosols emitted by forest fires in Portugal in August 2003 is clearly visible, which in itself is evidence for the ability of aerosols to perturb the radiative signal reaching the space-borne instrument. Over land and cloud-free oceans, the aerosol plume is brighter than the underlying surface, which indicates that aerosols increase the outgoing solar radiative flux at the top of the atmosphere, causing a negative RFari. In contrast, the northwestern section of the aerosol plume overlies bright clouds and appears darker, which indicates that aerosols decrease the outgoing solar radiative flux at the top of the atmosphere, causing a positive RFari.

Approximate formulas to quantify RFari in cloud-free sky have been derived, such as the following, which is valid for both scattering and absorbing aerosols:

$$\text{RFari} \approx ST^2 \varpi_0 \beta \Delta\tau [(1 - R_s)^2 - 2R_s(1 - \varpi_0)] / (\beta \varpi_0) \quad [1]$$

where S is the solar constant, in W m^{-2} , T is the dimensionless transmittance of the atmosphere above the aerosol layer, and R_s is the dimensionless reflectance of the surface. Aerosols are characterized by three dimensionless parameters:

- the change in optical thickness, $\Delta\tau$. The optical thickness, τ , measures the strength of aerosols scattering and absorption of radiation at a given wavelength and integrated over the atmospheric column;

Figure 4 Forest fires over Portugal on 3 August 2003, observed by the Moderate Resolution Imaging Spectroradiometer satellite instrument aboard NASA's Terra platform. Red dots mark the location of individual fires.

- their single-scattering albedo, ω_0 , which is the fraction of the optical thickness due to scattering processes, the remainder being due to absorption; and
- their upscatter fraction, β , which quantifies the fraction of radiation that is scattered upward with respect to the particle's horizontal plan.

Equation [1] highlights the fact that the sign of RFari depends on the aerosol absorption properties and the reflectance of the surface, as discussed above. It also shows that for a given set of optical properties, RFari depends linearly on the change in aerosol optical thickness or, equivalently, aerosol concentrations. The use of such simplified expressions has now been replaced by more sophisticated calculations based on radiative transfer numerical models, which are able to fully represent the strong dependences of RFari with the wavelength of the radiation and the solar zenith angle. Table 1 gives the globally and annually averaged estimate of RFari, obtained from global numerical models with representations of the life cycle and optical properties of aerosols. RFari is estimated at -0.4 W m^{-2} , with an uncertainty range of $\pm 0.5 \text{ W m}^{-2}$. Note the opposite signs of RFari exerted by scattering aerosols, such as sulfate, and absorbing aerosols, such as black carbon.

RFari triggers fast adjustments, which have historically been termed semidirect effects. The absorption of solar radiation by carbonaceous aerosols warms the aerosol layer while reducing the amount of downward radiation, cooling the surface. The combination of cooling at the surface and warming aloft modifies the stability of the atmosphere and the vertical profile of moisture. Cloud formation is in turn modified, which perturbs solar and terrestrial radiative fluxes, giving rise to the effective radiative forcing due to aerosol–radiation interactions (ERFari). The strength of ERFari compared to that of RFari depends in a complex way on the relative position of absorbing aerosols and clouds, and on the cloud regime. When absorbing aerosols overlie clouds, they stabilize the atmosphere and suppress convection, favoring stratocumulus cloud formation but hindering cumulus cloud formation. Absorbing aerosols located within low clouds reduce relative humidity and increase evaporation, reducing low cloud cover. Finally, when absorbing aerosols underlie clouds, they destabilize the atmosphere, promoting formation of convective clouds. Fast adjustments due to aerosol–radiation interactions are difficult to observe because aerosols and clouds are naturally correlated: aerosols are involved in cloud formation, clouds act as aerosol

sources via aqueous oxidation of aerosol precursors, and both aerosols and clouds are transported within the same air masses, thus correlating with meteorology. Estimates from global numerical models remain uncertain because of difficulties in representing convective processes at coarse resolution. Table 1 gives the globally and annually averaged estimate of ERFari, which at $-0.5 \pm 0.5 \text{ W m}^{-2}$ suggests that fast adjustments strengthen RFari on a global average.

Anthropogenic aerosols are not the only aerosol species that exert a RF by interacting with radiation under the definition of RF given in the Introduction section: because of their sporadic nature, aerosols emitted by volcanic eruptions are also considered external to the natural climate system. Large eruptions, such as those of Mount El Chichon in 1982 and Mount Pinatubo in 1991, inject sulfur dioxide directly into the stratosphere, where it is oxidized into sulfate aerosols. Aerosol residence time in the stratosphere is around 2 years, much longer than in the troposphere because of the absence of precipitation and slow air exchanges through the tropopause. Mount Pinatubo injected 20 Tg of sulfur dioxide, increasing stratospheric aerosol optical depths at $0.55 \mu\text{m}$ from their background level of less than 0.01 to more than 0.1. The resulting RFari in the solar spectrum has been estimated between -4 and -5 W m^{-2} on a global average. However, stratospheric aerosols also exert an RFari in the terrestrial spectrum, which is positive because they radiate energy at temperatures that are colder than that of the surface. For Pinatubo, the net RFari has therefore been closer to -2 W m^{-2} .

Aerosol–Cloud Interactions

The radiative forcing due to aerosol–cloud interactions (RFaci), termed alternatively aerosol first indirect RF, cloud albedo forcing, or Twomey forcing in the scientific literature, arises from the role aerosols play in the hydrological cycle as cloud condensation nuclei. The small sizes and soluble nature of most anthropogenic aerosols, especially sulfate, nitrate, and organic carbon aerosols, make them good nuclei upon which liquid cloud droplets form, although they are not good nuclei for ice crystal formation. In contrast to RFari, which is exerted by an increase in aerosol mass, RFaci is exerted by an increase in the number of aerosols that can act as cloud condensation nuclei. The distribution of a fixed amount of cloud water over those more numerous nuclei results in more, smaller cloud

Table 1 Globally and annually averaged best estimate and range of anthropogenic aerosol instantaneous RF (W m^{-2}) and ERF (W m^{-2}) over the period 1750–2000 due to aerosol–radiation interactions (ari), aerosol–cloud interactions (aci), aerosol on snow, and contrail formation

Anthropogenic aerosol species	RFari	ERFari	ERFari + aci	Aerosols on snow	Contrails

droplets (Figure 3(b)). More cloud droplets have a larger surface area, which increases the albedo of the cloud. Brighter clouds increase the outgoing solar radiation at the top of the atmosphere, exerting a negative RFaci. RFaci is exerted in the solar spectrum only, since by definition of the RF cloud albedo is the only factor that changes. An approximate formula for the computation of RFaci is:

$$\text{RFaci} \approx -S \cdot f \cdot \delta\alpha / \delta N_d \cdot \delta N_d / \delta N_a \cdot dN_a \quad [2]$$

where S is the solar constant, f is the fractional cloud cover, dN_a is the change in cloud condensation nuclei due to anthropogenic activities, $\delta N_d / \delta N_a$ is the sensitivity of cloud droplet number, N_d , to a change in cloud condensation nuclei, and $\delta\alpha / \delta N_d$ is the susceptibility of cloud albedo, α , to a change in cloud droplet number. RFaci is not linear with the change in aerosol number, and saturates at large aerosol number concentrations: a given change in aerosol number therefore exerts a stronger RFaci in pristine regions than in polluted regions. Numerous field studies have reported a dependence of cloud-base droplet size distribution with aerosol size distribution, demonstrating that the physical mechanisms behind RFaci occur in the atmosphere (Figure 5). However, the cloud liquid water content and geometric thickness never remain fixed in reality, making RFaci an abstract concept. Modeling studies have also challenged the assumption that anthropogenic emissions can only lead to an increase in the number of aerosols and cloud condensation nuclei. They propose that gas-phase precursors condense onto the additional aerosol particles provided by anthropogenic sources instead of creating new aerosols via nucleation. If confirmed, this mechanism opens the way for a decrease in cloud condensation nuclei in response to anthropogenic emissions, at least in regions where the number of particle available for condensation is low. RFaci would then be positive. The lack of observational constraints and the difficulty to adequately represent in numerical models the multiple scales involved in aerosol–cloud interactions make RFaci very uncertain. Because of the abstract nature of

RFaci and the difficulty of separating it from its fast adjustments, discussed below, recent publications do not estimate RFaci by itself, but include its fast adjustments.

Aerosol–cloud interactions in ice clouds are poorly known, both at the process level and because the characteristics and distribution of aerosols that make good ice nuclei remain unclear. However, emissions by aviation yield a particular kind of interactions with ice clouds, which deserve a specific mention. The aerosol and moisture emitted into the atmosphere by aircraft engines increase cloudiness by forming cirrus-like linear clouds called contrails. Contrail formation occurs when aerosols are emitted into an atmosphere, which is supersaturated with respect to ice. Depending on conditions, contrails evaporate or evolve into cirrus clouds, undistinguishable from naturally occurring cirrus, which complicates observational estimates of effective radiative forcing due to aerosol–cloud interactions (ERFaci) by contrail formation. Because high-level clouds are thin but radiate at a lower temperature than the surface, the contrail ERF is dominated by its terrestrial spectrum component, which is positive. Climate modeling studies estimate the contrail ERFaci at less than $+0.1 \text{ W m}^{-2}$ on a global, annual average. This weak value hides stronger regional forcings over the busiest aircraft corridors, especially the North Atlantic, where local temperatures may be affected.

The ERFaci is the sum of RFaci and its fast adjustments. Adjustments in liquid clouds posit that smaller cloud droplets take more time to reach the sizes required for the conversion of cloud water into rainwater, a process called autoconversion. A smaller autoconversion rate would then increase the lifetime of clouds and/or their vertical development. Observational evidence for fast adjustments is mixed, with observations showing either a reduction or enhancement of precipitation in regions with high anthropogenic aerosol loading, depending on cloud regime. Aerosol-driven fast adjustments are unlikely to influence those clouds whose lifetime is not regulated by precipitation, such as nonprecipitating stratocumulus clouds. At the other end of the precipitation spectrum, clouds where accretion of raindrops dominates over autoconversion are also not likely to be influenced by aerosol-driven changes in cloud droplet size distribution. Aerosol fast adjustments would then be limited to specific cloud regimes, or to situations where increases in cloud condensation nuclei forces a change in cloud regime, such as the transition from open- to closed-cells cumulus clouds. Because of natural correlations between aerosols and clouds, fast adjustments to aerosol–cloud interactions are difficult to observe unequivocally. In numerical models, estimates of ERFaci suffer from the difficulty in representing the cloud-scale processes involved. ERFaci is therefore very uncertain, with estimates ranging from -1.2 to 0 W m^{-2} .

Aerosol–Surface Interactions

Aerosols are removed from the atmosphere by turbulence and precipitation, and deposit onto the surface. In most cases, this deposition does not change the radiative properties of the surface. But the situation with snow- or ice-covered surfaces is different, as absorbing aerosols embedded into the snowpack reduce its albedo by up to 0.1 for large aerosol

Figure 5 Cloud droplet number concentrations (CDNC, in cm^{-3}) as a function of cloud condensation nuclei (CCN, in cm^{-3}) from observations of stratocumulus clouds off the coasts of California and Chile. Figure 2 of Hegg et al., 2012. Atmospheric Chemistry and Physics.

Figure 6 The reduction in wavelength-dependent snow albedo caused by increasing concentrations of black carbon aerosols in snow, for a snowpack with effective grain size of 200 μm . Figure 27, Bond, T.C., Doherty S.J., Fahey D.W. et al., 2013. Bounding the role of black carbon in the climate system: a scientific assessment. *Journal of Geophysical Research* 118, 5380–5552. doi:10.1002/jgrd.50171.

concentrations (Figure 6). Anthropogenic carbonaceous aerosols, and specifically black carbon, therefore exert a positive RF by darkening snow. This RF triggers amplifying fast adjustments: the warmer snowpack leads to increases in the mean grain size of snow, further decreasing surface albedo, while snow melts earlier in the spring, exposing the darker surface under the snow, again decreasing surface albedo. The ERF of aerosol–snow interactions is estimated between 0 and $+0.1 \text{ W m}^{-2}$ on a global, annual average for anthropogenic black carbon aerosols (Table 1). This weak global value hides large regional variations, with estimates of snow albedo RF being strong in the cold regions that are under sizeable influences from transported anthropogenic aerosols, most notably the Arctic and the Himalaya.

Another RF mechanism due to aerosol–surface interactions, albeit very indirect and poorly quantified, stems from competing aerosol radiative effects on vegetation productivity. On the one hand, aerosols decrease the amount of photosynthetically active radiation (a subset of the solar spectrum, ranging from 0.4 to 0.7 μm), which is used as a source of energy by plants. Aerosols are therefore detrimental to plant productivity. On the other hand, aerosol scattering of radiation makes solar radiation reaching the surface more diffuse, improving the distribution of sunlight between leaves under direct insolation and those in the shade. This effect favors vegetation growth. A modeling study of the carbon cycle obtained, by including those two effects, a 25% enhancement in vegetation productivity because of anthropogenic changes in aerosol concentrations over the period 1960–99. The associated increase in the land-based sink of carbon dioxide is however small, so the resulting RF is likely to be weak.

Total Aerosol RF

Estimates of the total aerosol RF and fast adjustment range from -1.9 to -0.1 W m^{-2} (Table 1) and a modeled distribution of aerosol RF is shown in Figure 7. The large uncertainty range highlights our lack of knowledge of present distributions of aerosol amounts and optical properties, and our limited understanding of aerosol RF and adjustment mechanisms, especially for aerosol–cloud interactions. PI aerosol distributions are also poorly constrained, affecting the reference state against which aerosol RF is defined. Nevertheless, it appears

Figure 7 Distribution of aerosol ERF, in W m^{-2} , obtained from numerical simulations based on changes in aerosol emissions over the industrial area. Figure 15 of Shindell et al., 2013. *Atmospheric Chemistry and Physics*.

that aerosols compensate a potentially large fraction of the RF exerted by increases in long-lived greenhouse gases and tropospheric ozone, which is estimated at $+2.6 \text{ W m}^{-2}$. How large that fraction really is has implications for estimating climate sensitivity to a doubling of carbon dioxide concentrations, which is an important property of the climate system. Because an increase in globally averaged surface temperatures is observed over the twentieth century, it follows that greenhouse gas RF is stronger, in absolute value, than aerosol forcing. Climate would need to be very sensitive to carbon dioxide increases to overcome a strong aerosol RF. Conversely, low climate sensitivity would be sufficient to overcome a weak aerosol forcing. Unfortunately, the large uncertainties in aerosol RF limit the usefulness of this method of estimating climate sensitivity.

Climate Response and Aerosol Feedbacks

Climate Response

The RF of aerosols and long-lived greenhouse gases triggers a change in the globally averaged surface temperature, which theoretically continues until a new radiative balance is reached. Although the temperature response of the climate system depends on the climate sensitivity, which is a property of the system, there is a small dependence on the forcing mechanism, because of the existence of fast adjustments. It is therefore useful to take the ratio between globally averaged surface temperature at equilibrium and RF, and compare that value to the corresponding ratio for a doubling of carbon dioxide concentrations. The resulting quantity is called efficacy:

$$\text{Efficacy} = (\Delta T_i / \Delta F_i) / (\Delta T_{2xCO_2} / \Delta F_{2xCO_2}) \quad [3]$$

Climate model estimates of efficacies for aerosol–radiation, aerosol–cloud, and aerosol–surface interactions are given in [Table 2](#) for selected aerosol species. Efficacies for absorbing aerosols are smaller than one because fast adjustments counteract the RF. In contrast, the RF due to darkening of snow from aerosol deposition has a large efficacy, which reflects how the location of the snow darkening RF, in the snowpack itself, promotes snowmelt compared to carbon dioxide, whose forcing is located, in effect, at the tropopause. The resulting surface albedo feedback, whereby the darker surfaces exposed by snowmelt further increase surface temperatures, is then stronger. Efficacies are useful on a global average, but hide differences in the geographical distribution of surface temperature changes ([Figure 8](#)). The positive temperature response to the RF by carbon dioxide exhibits maxima at high latitudes, because of increased poleward transport of heat and the surface albedo feedback from melting snow and ice. The pattern of the

negative temperature response to the RF by aerosols is different, being predominantly located over and downwind the anthropogenic aerosol source regions. Consequently, the temperature response to aerosol forcing is mainly located in the Northern Hemisphere. The different patterns of temperature response to long-lived greenhouse gases and aerosols are useful in detection and attribution studies.

Changes in surface temperatures are not the only manifestation of the climate response to anthropogenic forcing: precipitation and atmospheric dynamics also respond. The precipitation response is driven by the redistribution of energy within the atmosphere and at the surface. The existence of fast adjustments will therefore affect the precipitation response, and strongly absorbing aerosols such as black carbon are unique in their ability to decrease precipitation in spite of increasing surface temperatures. Dynamical responses are caused by changes in net radiative fluxes reaching the surface, and the gradient in RF between the two hemispheres. Anthropogenic aerosols are primarily located in the Northern Hemisphere, where they exert their radiative cooling. The Southern Hemisphere becomes relatively warmer, and modeling studies have repeatedly shown that this temperature gradient perturbs the Hadley circulation and causes a southward shift in the position of the intertropical convergence zone (ITCZ) and its band of strong precipitation. This mechanism may then have been a contributing factor to the severe droughts that affected the Sahel region of Africa in the 1980s. Studies using numerical models of the atmosphere–ocean system have also suggested links between the RF of aerosols and changes in dynamical features as diverse as the Indian monsoon or the multidecadal oscillation of North Atlantic sea surface temperatures.

Large volcanic eruptions have been useful opportunities to study the climate response to an aerosol RF. After the eruption of Mount Pinatubo, surface temperatures have decreased by 0.4 K globally for 2 years, which compares to a global increase of 0.6 K over the industrial period. Global reductions in precipitation have also been observed. In addition, the eruption of Mount El Chichon provided important information on the response of the ITCZ, because it preferentially loaded the Northern Hemisphere stratosphere, causing an interhemispheric RF and cooling gradient that shifted the ITCZ southward. The associated changes in rainfall may have exacerbated the Sahel drought of 1982 and 1983, as observed by monitoring stations and modeled numerically ([Figure 9](#)).

Aerosol Feedbacks

Natural and anthropogenic aerosol distributions are perturbed by the response of the atmosphere and ocean to anthropogenic RF, and this perturbation translates into further changes in the Earth's radiative budget, called aerosol radiative feedbacks. Feedbacks that exacerbate the initial RF are called positive feedbacks, while those that oppose the forcing are called negative feedbacks. For anthropogenic aerosols, feedbacks primarily arise from changes in wet removal by precipitation. The sign of those feedbacks remains unclear. Because precipitation is expected to increase in a warmer climate, one would anticipate an increase in wet removal and a decrease in the residence time of aerosols in the atmosphere. They would

Table 2 Efficacy of aerosol RF for selected species

<i>Aerosol species</i>	<i>Efficacy</i>
Sulfate (RFari + aci)	~1
Biomass burning (RFari + aci)	0.8–0.9
Black carbon (RFari)	<0.8
Black carbon (deposition on snow)	>2

Figure 8 Modeled patterns of surface temperature responses, in K, to PI increases in (a) sulfate, (b) biomass burning, and (c) black carbon aerosols, compared to (d) a doubling of CO₂ concentrations. Figure 2 of Jones et al., 2007. *Journal of Geophysical Research*.

therefore have less time to interact with radiation and clouds. However, models where low-cloud cover is suppressed by global warming suggest a feedback of opposite sign, because aerosols are then less likely to interact with clouds and be removed by precipitation. In addition, increase in convective

activity would loft aerosols higher up in the atmosphere, contributing to an increase in residence time in the atmosphere. Current climate models simulate weak feedbacks driven by changes in residence time, in the order of $\pm 0.2 \text{ W m}^{-2}$ per unit change in globally averaged surface temperature.

Feedbacks involving natural aerosols are potentially stronger, and their mechanisms are:

- Changes in vegetation cover: Fertilization by increased atmospheric concentrations of carbon dioxide is expected to increase vegetation productivity. Temperature-driven increases in occurrences of wild fires would have the opposite effect. Because vegetation emits biogenic volatile organic compounds that oxidize into secondary aerosols, changes in vegetation cover would translate into changes in natural aerosol levels and their interactions with radiation, clouds, and ultimately vegetation productivity, closing the feedback loop. In addition, the import of nutrients, such as phosphorus from transported mineral dust aerosols, is important to rain forest ecosystems, and will change in the future as the sources and sinks of those aerosols respond to climate change. The sign of net aerosol-vegetation feedbacks is currently unknown.
- Changes in ocean biogeochemical activity: Ocean phytoplankton is a strong source of dimethylsulfide (DMS), a gas that is partly oxidized into sulfur dioxide, itself a gaseous precursor of sulfate aerosols. Global warming of sea-surface temperatures has competing effects on DMS production. On the one hand, it reduces ocean nutrients and decreases phytoplankton productivity and DMS emissions. On the other hand, it reduces the depth of the ocean mixed layer, increasing seawater DMS concentrations and DMS emissions into the atmosphere. Climate models simulate a net increase in sulfate aerosols produced by ocean-based DMS emissions with increased temperatures. The aerosol-radiation and aerosol-cloud interactions exerted by those additional sulfate aerosols would be a negative feedback, termed CLAW feedback after the initials of the scientists who proposed the feedback loop, Robert Charlson, James Lovelock, Meinrat Andreae, and Stephen Warren. The numerical models that include the CLAW mechanisms, however, suggest a feedback weaker than initially thought, because of the presence of multiple bottlenecks between increased DMS emissions and increased aerosol radiative effects.
- Changes in sea-ice cover: Increased surface temperatures lead to a retreat of sea-ice, which opens the ocean for emission of DMS precursors and primary sea-salt aerosols. Those aerosols then interact with radiation and clouds to produce a negative feedback.
- Changes in bare-soil cover: Desertification leads to increased emissions of mineral dust aerosols, although the magnitude of this response also depends on changes in near-surface wind speed. Such increases would exert a radiative feedback because mineral dust aerosols interact with solar and terrestrial radiation, and are good ice-cloud nuclei. Mineral dust aerosols also supply nutrients to vegetation and oceanic phytoplankton, and changes in mineral dust deposition to those ecosystems would affect their productivity.

Current estimates of those natural aerosol feedbacks suffer from our lack of knowledge of present-day natural aerosol sources, and the limited representation in numerical models of the multiple mechanisms involved. Consequently, uncertainties are large, but natural aerosol feedbacks are potentially strong.

Aerosol-Based Mitigation of Climate Change

Anthropogenic aerosols provide means of mitigating climate change. Since scattering aerosols exert a negative RF, maintaining the associated anthropogenic emissions at their present levels offsets the positive RF by long-lived greenhouse gases, and slows down the rate of increase in globally averaged surface temperatures. Unfortunately, the same anthropogenic emissions decrease air quality and are detrimental to human health, which is strong argument for decreasing emissions further, to the expense of a reduced aerosol-driven climate cooling. Indeed, most scenarios of future changes in anthropogenic aerosol emissions assume strong decreases because of the enforcement of increasingly ambitious air quality standards. From this point of view, black carbon aerosols become attractive targets for climate mitigation: decreasing their emissions, in particular from combustion of fossil fuels, would mitigate climate change, because they exert a positive RF, and benefit air quality, because they are pollutants. The short residence time of black carbon aerosols in the atmosphere also means that those benefits would manifest quickly. The situation is, however, complicated by the fact that fossil fuel combustion also emits sulfate and organic carbon aerosols, which have a cooling effect on climate. Accounting for those co-emitted species severely decreases the net RF of black carbon, from a strong $+1.1 \text{ W m}^{-2}$ to a weaker $+0.2 \text{ W m}^{-2}$ according to a scientific review.

Aerosols are also involved in climate engineering proposals, where the radiative budget of the Earth is deliberately altered to counteract the positive RF by long-lived greenhouse gases. One such proposal, publicized by Nobel Prize winner Paul Crutzen in 2006, is to replicate large volcanic eruptions by injecting sulfur dioxide in the stratosphere. The eruption of Mount Pinatubo has provided a useful analogue and showed that such an injection would be able to reduce global surface temperatures. Another proposal relies on aerosol-cloud interactions by injecting sea-spray aerosols into stratocumulus decks in the hope of making those clouds brighter. Aerosol-based climate engineering proposals have the advantage to be less costly than adapting to climate change, and can be calibrated to offset positive RFs of varying strengths by varying the amount and size of the aerosols emitted. They are however imperfect, because they do not address nonradiative consequences of increases in carbon dioxide concentrations, such as ocean acidification. Climate engineering techniques are also known to trigger unwanted regional changes, which are potentially worse than nonengineered climate change. Those unwanted changes result from the difficulty of perfectly offsetting the greenhouse gas RF in terms of geographical, vertical, spectral, and temporal distributions. Changes in precipitation patterns are especially problematic, although aerosol climate engineering could be calibrated to minimize precipitation changes by allowing a small amount of global warming. In the event that carbon dioxide emissions cannot be reduced, humanity would enter into a long commitment to climate engineering, because climate modeling studies have shown that switching off climate engineering leads to a rapid warming of surface temperatures, which are back to

nonengineered levels within a decade. Specific techniques also have their own drawbacks. For example, it remains unclear how stratospheric ozone would respond to long-term injections of sulfur dioxide, and what the effects of a large-volcanic eruption on an engineered stratosphere would be.

Introduction

Soot (also often called black carbon, charcoal, elemental carbon, or graphitic carbon) is produced by incomplete combustion of carbonaceous materials. Soot is found everywhere on Earth, including the atmosphere, oceans, sediments, soil, and ice sheets. It is also found in meteorites, may be present in asteroids and comets, and is believed to be responsible for dark absorption bands observed in stellar spectra. Soot is even suspected of participating in the initiation of life processes.

In the atmosphere, particularly in the boundary layer, soot is a major component of aerosols that strongly absorb solar radiation. Soot particles, when combined with sulfates, nitrates, sea salt, and organic particulate carbon present in the atmosphere, can serve as cloud condensation nuclei. Soot particles inside cloud droplets increase the absorption of solar radiation by droplets and modify droplet size distribution. Soot also provides a suitable surface and serves as a catalyst for various atmospheric heterogeneous chemical reactions. Thus soot is an important constituent of the atmosphere that affects atmospheric chemical composition and atmospheric radiation balance through both its direct effects (absorption and scattering of solar radiation) and its indirect ones (modifying the formation and lifetime of clouds and the size distribution of droplets).

Soot contributes to atmospheric pollution. It reduces visibility and is also blamed for a variety of adverse health effects including a long list of respiratory diseases and various cancers.

The main sources of soot in the atmosphere are biomass burning and fossil fuel combustion. Soot is the only material suspended in the atmosphere with a long residence time (up to 10 days) that strongly absorbs electromagnetic radiation of all wavelengths. Other atmospheric aerosols have either a very low absorption (sulfates, nitrates, sea salt and organic particulate matter) or a moderate absorption (soil and mineral dust) at visible wavelengths. From this follows the unique role of soot in the atmosphere as the only component of the atmospheric aerosol which strongly absorbs the visible part of solar radiation.

Carbon is a major component of all living material. Carbonaceous particles produced by biomass burning or fossil fuel combustion span a large range of sizes. Particles with diameter over 10 μm are subject to fast gravitational settling and are removed from the atmosphere within a short distance from their sources. On the other hand, submicrometer-sized particles remain suspended in the atmosphere for several days and are transported over long distances. Black carbon (soot) has been found at all places on the globe, including the most remote areas in Antarctica.

Carbon has atomic number $Z = 6$. There are two stable carbon isotopes, ^{12}C and ^{13}C , and four radioactive ones: ^{10}C , ^{11}C , ^{14}C , and ^{15}C . The ^{14}C isotope is used for carbon dating. The carbon atom has 6 electrons, and 4 of them are in the outer (2S and 2P) electron shells. These 4 valence electrons are available to form stable covalent bonds (shared pairs of electrons between 2 neighboring atoms) with other carbon atoms or atoms of other elements. Carbon atoms can thus form chains or rings of high complexity. If all 4 electrons are used in covalent bonds, the resulting materials are generally transparent in the visible part of the electromagnetic spectrum. On the other hand, if not all valence electrons are used for covalent bonds then the unused electrons can form a cloud of non-localized electrons, as in graphite, and the material will start showing a definite degree of absorption and anisotropic electric conductivity.

There is an enormous variety of organic compounds of carbon. They are compounds primarily of carbon with oxygen, hydrogen, and nitrogen, although compounds with a number of other elements, including sulfur, phosphorus, and halogens, are also formed. When heated, all organic substances have one thing in common: they always produce, in addition to steam and carbon dioxide, a black material commonly called the char, soot, black, or elemental carbon. This is due to the fact that almost all of the combustion processes taking place are incomplete (oxygen-deficient): they do not provide sufficient oxygen for the full oxidation of the fuel, and generally some of the carbon will end up in a condensed phase rather than in gaseous oxide form.

Graphite and Black Carbon

The two basic forms of solid elemental carbon are diamond and graphite. They differ from each other in the form of lattice structure into which carbon atoms are arranged. This difference leads to vast dissimilarities in physiochemical and optical properties between the two carbon forms.

Graphite has a structure of a planar hexagonal lattice with 4 carbon atoms per primitive cell. Within the lattice plane each carbon atom is bound to 3 neighboring atoms by strong covalent bonds. The 4 valence electron of each atom contributes to a relatively weak bond between planes of hexagonal lattices. These electrons are not bound to any particular carbon atom (nonlocalized electrons) and they can move relatively freely within a periodic potential formed by a hexagonal lattice of carbon atoms in graphite. Nonlocalized electrons are responsible for good electric conductivity of graphite in the basal plane of the hexagonal structure and for its absorption properties in the visible part of the electromagnetic spectrum.

Separation between lattice planes is about 2.4 times the nearest neighbor distance (about 0.142 nm) within the plane. Graphite is often called a semimetal, indicating that it has some properties similar to that of metals. However, its effective density of charge carriers is of order 10^{18} cm^{-3} ; several orders of magnitude below that of typical good metals (10^{22} cm^{-3}).

In the diamond lattice, the 4 nearest neighbors form the vertices of a regular tetrahedron; all 4 valence electrons of each carbon atom are used to form strong covalent bonds with the four nearest neighbors. There is no planar anisotropy and no free electrons. A diamond is an extremely hard, high-density, transparent nonconductor.

The basic characteristic of graphite and the basis of its high absorption in the visible part of the spectrum is its planar hexagonal structure. Whenever a sufficiently large number of carbon atoms get arranged in the form of a planar hexagonal lattice, some electrons will be only weakly bound to their respective atoms; they will form almost a free electron cloud and the material will manifest an increased conductivity and light absorption. This happens even if there are other atoms involved with carbon, as long as the number of other atoms is relatively small (usually below 20% by mass). Such a material, which is not a pure graphite, but at least partially manifests the basic graphite characteristics (elevated conductivity and increased absorption at visible wavelengths), is generally referred to as black carbon. There are two ways in which carbon atoms can be induced into the planar hexagonal lattice: either through a process of soot formation (high-temperature combustion) or by charring (lower-temperature burning).

Particulate Emission by Fossil Fuel and Biomass Burning

Particulate material ejected into the atmosphere during combustion processes contains soot, charcoal and ash. Ash originates from an inorganic component of fuel. Its mass is usually small (around 1%) compared with the mass of other forms of particulate matter ejected to the atmosphere. Unburned hydrocarbons react with atmospheric oxides of nitrogen and solar radiation to form smog.

Soot

Soot production generally proceeds through condensation of vaporized organic matter, usually through a number of polycyclic aromatic hydrocarbons (PAH). This is a complex process involving, first, the production of benzene and acetylene from the original biomass of fossil fuel. It is believed that most fuels break down into the same species at the beginning of the sooting process. In the second step of soot formation, the acetylene and benzene are transformed into the phenyl, a simple aromatic hydrocarbon with just one ring. The chain of aromatic rings then grows through a fast polymerization process (replacement of hydrogen atoms by C_2H_2 groups). With an increasing number of aromatic rings, a nucleus of a soot particle is formed. Some models consider four rings to be sufficient for soot nucleation. Thus the soot is produced by gas to particle conversion. A typical size of a soot nucleus is a few nanometers. The nucleus grows by additional condensation

and coagulation. Freshly produced soot particles are almost spherical and they have tendency to form, through coagulation, chainlike structures with fractal geometry (Figure 1), with a fractal dimension of about 1.8. Soot production takes place at high temperatures, above 1000°C , during the fossil fuel combustion or during the flaming stage of biomass burning.

A mature soot particle is typically composed of a stack of layers, each of them having a graphite-like hexagonal structure. Not all layers are arranged in a parallel fashion. In addition to carbon, soot contains remnants of other elements present in the original fuel. A typical carbon content of soot is between 90 and 98%. Soot X-ray analyses indicates the presence of a regular graphite structure throughout the soot volume.

Generally, fuels with higher C/H (carbon-to-hydrogen) ratio produce more soot. For a given amount of fuel, the variable flow conditions produce more soot than a steady-flow regime. Soot can also be produced by the oxidation of almost pure elemental carbon. At high temperatures, a carbon vapor is formed, which in colder regions, away from the flame, condenses to form solid carbon structures. In this way graphite-like soot as well as the famous fullerenes C_{60} and C_{70} are formed.

Charcoal

Charring of organic materials starts at temperatures considerably lower than that of soot formation. Burning of food during cooking (i.e., the production of nicely black toast) is an example of low-temperature charring. At temperatures above about 300°C , most of the organic materials undergo a slight thermal decomposition; hydrogen and other noncarbon elements are stripped from carbon chains and rings and the carbon condenses into a graphite-like structure. The density of black porous residuum depends on the mass ratio of carbon to other elements in the original material.

X-ray analysis confirms that at temperatures above 300°C the hexagonal, graphite-like structure begins to form. This structure becomes more evident and more regular with an increasing temperature of oxidation. As hydrogen and other elements (e.g., nitrogen and sulfur) are released to the atmosphere and carbon atoms start forming the basic planar hexagonal structures, the optical properties of the material

Figure 1 Morphology of freshly produced soot, showing a characteristic chain-like structure of nanometer-size soot particles.

Figure 2 A typical black carbon (charcoal) particle structure from a coal-fired power plant. Photograph by R. Cheng; reproduced with permission from Chylek P, Ramaswami V, Pinnick R, and Cheng R (1981). Optical properties and mass concentration of carbonaceous smokes. *Applied Optics* 20: 2980–2985.

undergo a drastic transformation. With an increasing number of planar hexagonal rings, there is an increasing number of nonlocalized, almost free, electrons, and the material starts showing some of the graphite characteristics, especially an increased absorption of visible electromagnetic radiation. Original organic material becomes dark brown or black.

In the case of biomass burning the charring process takes place during the smoldering phase. Fossil fuel combustion often produces carbonaceous particles that are in a form of hollow spheres (cenospheres) or of spongy spherical structures (Figure 2 and Figure 3).

Figure 3 Black carbon (charcoal) particle structures from an oil-fired power plant. Photograph by R. Cheng; reproduced with permission from Chylek P, Ramaswami V, Pinnick R, and Cheng R (1981). Optical properties and mass concentration of carbonaceous smokes. *Applied Optics* 20: 2980–2985.

The sizes of particles produced by charring are from sub-micrometer to several hundred micrometers. Smaller sizes are uplifted during the turbulent conditions produced by localized heating. They reside in the atmosphere for an extended time and are transported over long distances.

Organic and Black Carbon

Regarding aerosol radiative effects, the total carbon in atmospheric aerosols (excluding inorganic carbon in the form of carbonates as a part of soil and mineral dust particles) is usually divided into so-called organic and black carbon. This division is based not on aerosol chemistry, but rather on the aerosol optical properties. Carbon of atmospheric carbonaceous aerosols that absorbs visible radiation strongly is called black carbon; the remaining carbon (carbon of nonabsorbing carbonaceous particulate matter) is organic carbon. The black carbon defined in this way contains pure graphite (elemental carbon), soot, and charcoal as well as their internal mixtures and their mixtures with organic carbon. Black carbon generally resists oxidation at temperatures below about 400 °C, while organic carbon is oxidized easily at lower temperatures.

The separation of total carbon into organic and black carbon is not unambiguously defined chemically. Some of more complex organic compounds may show a substantial absorption in the range of visible wavelengths. Should they be a part of organic or of black carbon? If we are interested in radiative effects of carbonaceous aerosols then all absorbing material should be kept in a category of black carbon. On the other hand, if we are interested in chemical reactions of organic aerosols then we may keep even absorbing organic compounds in the inventory of organic (rather than black) carbon. From the point of view of absorption of solar radiation in the atmosphere, it is reasonable to divide the total carbon into organic and black carbon, even if this division is not chemically well defined.

Black Carbon Measurements

Black carbon (soot) properties, such as density, absorption coefficient, size, and morphology are highly variable. They depend on conditions of generation, source strength, atmospheric transport, transformations due to mechanisms such as catalytic surface reactions, and their degree of mixing of black carbon with other atmospheric particles as well as of their removal due to wet and dry deposition processes.

Measurements of mass concentration, absorption, and size distribution of black carbon are relatively sparse up to the late 1970s, owing mainly to lack of suitable instrumentation.

An increased interest in the role of soot in the atmosphere brought about the development and evaluation of new analytical methods and measuring techniques.

Mass Concentration and Size Distribution

Most soot size distribution measurements have been obtained from filter samples using multistage impactors combined with either conventional or transmission and scanning electron

Table 1 Summary of black carbon (soot) measurements

Region	Extinction coefficient (m^{-1})	Mass concentration ($\mu\text{g m}^{-3}$)
Remote (Antarctic/Arctic)	1×10^{-8}	0.001
Mid troposphere	$1\text{--}3 \times 10^{-8}$	0.001–0.003
Marine	$1\text{--}5 \times 10^{-7}$	0.01–0.05
Rural/continental	$1\text{--}5 \times 10^{-6}$	0.1–0.5
Urban	$1\text{--}4 \times 10^{-5}$	1.0

microscopy. More recent techniques include the use of an optical scattering aerosol sizing probe equipped with a heated intake.

Soot particle size resides predominantly in the sub-micrometer accumulation mode regime, with a geometric mean diameter in the range 0.05–0.2 μm and with a geometric standard deviation 1.33 to 2.0. The average particle size increases with time during long-range atmospheric transport.

Typical soot mass concentration values (Table 1) range from about 1 ng m^{-3} for remote Antarctic locations to more than 1 $\mu\text{g m}^{-3}$ for polluted urban air. The number concentration varies from about 0.1 to $>100 \text{ cm}^{-3}$.

The mass extinction coefficient in polluted urban environments has typical values in the range 10^{-3} to 10^{-4} m^{-1} , while representative values for a more remote atmosphere are $\leq 10^{-5} \text{ m}^{-1}$.

Black Carbon in Precipitation

The removal of black carbon from the atmosphere is believed to be primarily by wet deposition. However, there are only a few measurements of black carbon concentration in rain and snow. The method used consists of the filtering of collected precipitation through quartz fiber filters, followed by a thermo-optical method of determination of the amount of black carbon on the filter. The range of black carbon concentration measured in rainwater and in snow is summarized in Table 2.

Black Carbon in Ice Cores

Ice cores preserve the information concerning the state of the atmosphere at the time of snow deposition (analysis of ice and aerosols) and at the time of enclosure of air bubbles (analysis of gases trapped in bubbles). Black carbon concentration in ice

Table 2 Black carbon concentration in cloud water and in precipitation

Type of cloud or precipitation	Black carbon ($\mu\text{g kg}^{-1}$)
Marine Stratus, North Atlantic	8–60
Stratocumulus, eastern Pacific	20–80
Rain Water, eastern Canada	1–11
Rain Water, Seattle	3–400
Snow, eastern Canada	1–32
Snow, New Mexico and western Texas	5–16
Snow, Cascade Mountains	22–59
Snow, Camp Century, Greenland	2–3
Snow, Antarctica	0.2

cores can be used to deduce the information concerning the past climate and the effect of man's activities on the atmosphere.

The black carbon concentration changes in Alpine glaciers indicate the increase of atmospheric black carbon concentration due to an increase in the regional industrial activities. On the other hand, no increase in black carbon concentration has been found in several analyses of Greenland ice cores. A comparison of black carbon (soot) concentrations found in the Greenland Summit GISP2 (Greenland Ice Sheet Project 2) ice core dated to around the years 320–330 AD and recent (1989–1990) snow from the same location suggests the same average concentration of about 2 ng g^{-1} (Figure 4).

Optical Constants of Black Carbon (Soot)

Determination of the complex refractive index $m = n + ik$, where i is an imaginary unit, n and k are real and imaginary parts of refractive index, respectively, is a difficult task for soot or atmospheric black carbon. A number of different approaches have been made to determine the refractive indices of soot carbon.

One of the principal methods used has involved the measurement of reflectivity of electromagnetic radiation from polished soot-like materials. Reflectivity methods have been applied to soot material, which has been compressed into pellets with nearly specular surfaces. The compression does not result in a uniform carbon material, but contains voids, which have to be considered in the determination of the optical constants.

A combination of transmission and reflection has been used on an amorphous thin film of carbon. Another approach has involved extinction measurements for a suspension of carbon particles (of mean diameter 75 nm), which overcomes uncertainties associated with purity, crystal microstructure variations and void fraction of the sample. Indirect determination of the refractive indices of flame soot has been carried out *in situ* using

Figure 4 Comparison between soot concentrations (ng g^{-1}) in the Greenland Summit GISP2 ice core dated about 320–330 AD with that in recent snow (1989–1990) from the same location. There is no change of an average soot concentration in remote Greenland location between the current snow and the ice core more than 1700 years old. Large, ancient forest fires somewhere in the Northern Hemisphere are represented by peaks in soot concentrations around the years 324 and 326 AD.

Table 3 Black carbon optical constants (real and imaginary part of refractive index) in the 0.35–1.5 μm wavelength range

Material	Real part	Imaginary part	Method of measurement
Amorphous carbon	1.85–2.8	1.2–0.9	Transmission, reflection
Carbon black	1.92	0.95	Extinction
Polycrystalline graphite	2.24	1.04	Fresnel reflection
Coal samples	1.6–2.1	0.3–0.5	Reflectance
Soot	1.5–1.9	0.4–0.8	Reflectance

light scattering combined with extinction measurements. However, the soot particle size and number concentrations were not measured directly.

A summary of measured optical constants of soot is presented in Table 3. The variability in the data can be attributed largely to factors such as degree of sample homogeneity, compositional change such as C/H ratio, density, sample preparation, etc. Recommended values for the refractive index of black carbon within the wavelength range from 0.3 to 1.5 μm (measurements indicate that the parameters do not greatly change with wavelength in the solar spectrum region) are: $m = (1.9 \text{ to } 2.0) + i(0.7 \text{ to } 1.0)$.

Effect of Soot on Radiative Properties of Aerosols and Clouds

When soot gets incorporated inside cloud droplets or within a composite aerosol particle (to form an internally mixed aerosol) it modifies their radiative properties. The main effect of soot is to increase the absorption by droplets and aerosol particles. Since soot exhibits a strong absorption at all wavelengths from UV to far infrared, while liquid water has a strong absorption only in the infrared region, it is mainly the absorption of the visible and UV radiation that is enhanced by the presence of soot. Consequently, the presence of soot will decrease the single scattering albedo, ω , at visible wavelengths of cloud droplets and aerosol particles.

The intensity of the electromagnetic field within a water droplet or sulfate aerosol is higher than the intensity in free space, owing to the focusing effect of the droplet. On average, a soot particle within a droplet, or as an internally mixed aerosol, will absorb more than twice as much of the incoming radiation than (externally mixed) soot in the free atmosphere.

Effective Medium Approximation

The single scattering albedo (the ratio of the scattering to the sum of the scattering and absorption cross-sections) of a spherical aerosol particle or water droplet can be calculated using the standard Mie scattering formalism. Mie scattering calculations require as input the size of a spherical particle and its refractive index. A refractive index of a composite particle (a droplet of given material with soot inclusions inside) can be calculated using an effective medium approximation. For soot inclusions considerably smaller than the wavelength of a considered radiation, the Maxwell–Garnett effective medium

approximation with soot inclusions surrounded by water matrix (or other material of the original particle) is an appropriate form of an effective medium approximation. The effective refractive index, m_{eff} , of a composite droplet is given by

$$m_{\text{eff}}^2 = m_0^2 \left(1 + \frac{4f(m_c^2 - m_0^2)}{m_c^2 + 2m_0^2 - 2f(m_c^2 - m_0^2)} \right) \quad [1]$$

where m_0 and m_c are refractive indices of a matrix material (water or sulfate) and soot inclusion, and f the soot volume fraction. The single scattering albedo of a composite water–soot or aerosol–soot particle is then obtained by applying the Mie scattering formalism to a homogeneous particle whose optical properties are described by an effective refractive index.

Soot and Direct Radiative Effect of Aerosols

Soot incorporated within an aerosol particle will increase the particle's absorption in the visible part of solar spectrum and thus it will decrease the particle's single scattering albedo. The direct top of the atmosphere radiative forcing, ΔF , of an optically thin aerosol layer is given by

$$\Delta F = -\frac{S_0}{4} T_{\text{atm}}^2 (1 - N) [(1 - a)^2 2\beta\tau_{\text{sc}} - 4a\tau_{\text{abs}}]. \quad [2]$$

where S_0 is the solar constant, N the fraction of sky covered by clouds, T_{atm} the transmittance of the atmosphere above the aerosol layer, a the surface albedo, β the fraction of the scattered radiation that is scattered into the upper hemisphere, and τ_{sc} and τ_{abs} the scattering and the absorption optical thickness of an aerosol layer.

The negative value of radiative forcing implies cooling of the system, while a positive value implies heating. For non-absorbing aerosol $\tau_{\text{abs}} = 0$, and eqn [2] implies always a cooling effect. When soot is present within an aerosol, aerosol absorption increases and the direct aerosol effect will be either cooling or heating, depending on the relative magnitudes of the terms inside the bracket on the right-hand side of eqn [2]. For an optically thin aerosol layer, $\omega = \tau_{\text{sc}}/(\tau_{\text{sc}} + \tau_{\text{abs}})$. The critical single scattering albedo, ω_{cr} , which determines whether an aerosol will heat or cool the system, is derived from eqn [2] in the form

$$\omega_{\text{cr}} = \frac{2a}{\beta(1 - a)^2 + 2a} \quad [3]$$

For given surface albedo, a , and backscattering fraction, β , an aerosol with single scattering albedo $\omega > \omega_{\text{cr}}$ will cool the system, while aerosols with $\omega < \omega_{\text{cr}}$ will cause heating.

Thus the sign of a direct top-of-the-atmosphere aerosol forcing depends – in addition to the fraction of radiation scattered into the upward hemisphere and the albedo of an underlying surface – on the amount of soot within an aerosol particle (which determines the single scattering albedo ω). Most aerosols will cause cooling over the ocean and heating over fresh snow. Thus, the soot heating effect will be especially significant over clouds, ice, and snow.

Soot and Absorption of Solar Radiation by Clouds

Soot within cloud droplets will again increase the droplets' absorption of electromagnetic radiation and decrease their

Figure 5 Cloud reflectivity as a function of radiation wavelength for an optically thick (semi-infinite) cumulus cloud. The cases of pure water cloud droplets and for varying soot volume fractions in cloud droplets are shown. Adapted with permission from Chylek P, Ramaswamy V, and Cheng RJ (1984). Effect of graphitic carbon on the albedo of clouds. *Journal of the Atmospheric Sciences* 41: 3076–3084. A significant reduction of cloud reflectivity at visible and near-infrared wavelengths is obtained for soot volume fractions at and above 10^{-6} .

single scattering albedo. This leads to an increased absorption of solar radiation within a cloud layer, to heating, and to a possible increased rate of evaporation of cloud droplets.

A small amount of soot, of the order of 10^{-9} to 10^{-7} by volume, in cloud droplets has little effect on cloud optical

properties. However, soot in highly polluted regions, produced by industrial activities or biomass burning, can affect cloud absorption. Soot in cloud water concentration of the order of 10^{-6} and above will increase cloud absorption significantly. The effect of soot volume fraction, varying from 10^{-7} to 10^{-4} , on the reflectivity of cloud is quite pronounced at visible wavelengths, as shown in Figure 5. Most accumulation-size soot particles can propagate up to several thousands miles away from their sources without a significant decrease in soot concentration. Thus, for example, an extensive biomass burning can affect cloud absorption and regional climate in regions several hundred miles away from source.

Synopsis

Agricultural meteorology draws on basic physical and biological sciences to discover, define, and apply knowledge of weather and climate to production of food-, feed-, fiber-, and bio-based products. Agricultural meteorology is based on fundamental principles of radiation and surface aerodynamics and thermodynamics. Models of atmospheric interactions with plants and soil, made more applicable by expanding historical databases, find increased application in risk management and climate change. A highly trained workforce in agricultural meteorology is needed to address future needs for global food security in a changing global climate.

Introduction

Agricultural meteorology is an interdisciplinary science concerned with discovering, defining, and applying knowledge of the interactions between meteorological and hydrological factors and biological systems to practical use in agriculture. An ultimate goal of agricultural meteorology is to extend and fully deploy knowledge of atmospheric and related processes to optimize agricultural production, and hence to increase profitability, decrease risk, contribute to biofuel production, and feed an expanding global population. A second goal that is taking on increased importance is to help conserve natural resources and protect our soil, plant, and water resources.

Environmental interactions of a wide range of agriculturally related organisms are of interest to agricultural meteorologists. Although most attention has been focused on agricultural and horticultural crops and forests, this segment of atmospheric science also includes environmental interactions with animals grown to provide food and fiber, insects, plant and animal pathogens, and aquaculture species. Agricultural meteorology, like the entire field of meteorology, has its roots in the study of temperate (midlatitude) regions of the northern hemisphere. In parallel with its parent discipline, agricultural meteorology has more recently intensified its focus on tropical agriculture, with some of the same difficulties of paucity of data faced by tropical meteorology.

The vagaries of weather always have been a leading cause of variability in agricultural production, but the technological era has increased this vulnerability even as it has provided some means of insulating agriculture from adverse conditions. So, for instance, disease-resistant crops, wide availability of soil amendments and chemicals for pest control, and efficient tillage, planting, and harvesting equipment have reduced agricultural vulnerability and increased yields; however, larger fields and wide use of monocultures have exposed crops to vector-borne diseases and insects and exposed soil to erosion by wind and water. The use of chemicals, new varieties, and genetically modified organisms has brought new weather dependencies.

Agriculture is arguably the most weather-sensitive sector of society. Forty percent of the land surface of the Earth is classed as arid, semiarid, and dry subhumid but is home to millions of people, particularly in developing countries. For some of these areas, frequent crop failure due to adverse weather must be

a part of interannual planning by farmers and regional and state policy makers. International agricultural meteorologists, therefore, have significant concern for famine and food security because of their close link to interannual variability of weather and climate. Even in areas having what are considered ideal climates for crops, water management is a major concern, particularly in regions where competing uses of fresh water put increased pressure on agricultural uses of water.

The historical focus of agriculture to produce food and fiber for an expanding global population has been supplemented by a new thrust at the beginning of the twenty-first century. Agriculturists now also have roles in managing soil and landscapes to regulate flows of carbon, nutrients, soil amendments, and pesticides. Atmospheric transport of pesticides, spores, and pollens (particularly those originating from genetically modified plant materials) must be quantified with increased accuracy. Although uncertainty remains large, consensus estimates of sources and sinks of greenhouse gases such as carbon dioxide, methane, and nitrous oxide reveal that agriculture has a significant role. For instance, agricultural sources of methane from ruminant animals, rice production, and biomass burning are comparable to, or may exceed, natural emissions on a global scale.

Agriculture may play a significant role in moving society from its fossil-fuel base for energy and materials to one that relies more heavily on bioenergy and biobased materials. Tillage practices on natural prairie lands have reduced soil carbon by up to 50% in the US Midwest. Opportunities for agricultural recapture of soil carbon by use of high-yield plant varieties, reduced tillage, and improved management of crop residues, fertilization, and irrigation are under consideration.

Most biological and chemical processes in the biosphere are highly temperature and moisture dependent, and meteorology is the study of underlying physics and chemistry that governs these processes. Emerging recognition of the importance of biocomplexity and ecosystem services and the need for sustainable methods of agriculture and economic development are creating new roles for agricultural meteorology. Agricultural meteorologists, therefore, can be expected to play an increasingly larger role in working with scientists from many disciplines to meet the challenges of these new environmental concerns.

Fundamental Principles

Radiation

Agricultural meteorology is built on a foundation of fundamental physical laws with applications to the plant, animal, and soil environments. The principles of radiation describe how radiant energy received directly from the sun and in diffuse form from the atmosphere is made available to plants for photosynthesis and converted by solid and liquid surfaces into other forms of energy. Approximately 40% of the radiation emitted by the Sun is in the visible wavelength band from 0.4 to 0.7 μm , sometimes referred to as the shortwave band or, for biological applications, as the band of photosynthetically active radiation (PAR). Radiation with wavelengths just shorter than those in the PAR zone is called ultraviolet radiation (UV-A from 0.32 to 0.40 μm and UV-B from 0.28 to 0.32 μm). Ultraviolet radiation is not used by plants for photosynthesis, but it can damage living tissue of plants and animals, particularly simple organisms.

Visible radiation may arrive at a leaf surface either directly from the Sun or indirectly by reflection from atmospheric molecules, clouds, or solid or liquid surfaces (including other plant leaves). Leaf orientations and solar zenith angle cause the amount of radiation received to vary over the course of the day. The fraction of plan area of leaves to ground area covered by the plant (including only one side of the leaf) is called the leaf area index and is used to describe the area of the plant available for photosynthesis.

Radiation of wavelengths just larger than visible light is called longwave or infrared radiation, with the band from about 0.7 to 1.5 μm being referred to as the near-infrared region, which accounts for about 40% of the solar spectrum. Wien's displacement law (eqn [1]) relates the wavelength of radiated energy to temperature.

$$\lambda = \frac{2897}{T} \quad [1]$$

In eqn [1], λ is the wavelength (in μm) and T is the temperature in K. Wien's law can be used to show that most terrestrial surfaces emit radiation of 8–12 μm , with most growing plants radiating at about 10 μm . The amount of dry matter produced by a plant per unit absorbed PAR is a measure of its light-use efficiency, with typical values being from 1.5 to 4.5 g dry matter per megajoule. Chlorophyll in leaves makes plants much less reflective in the PAR region than in the near-infrared (by a factor of 4 for corn and soybeans), a fact that allows remote assessment of photosynthesis by use of the normalized difference vegetation index derived from satellite observations.

Heat Balance

Thermodynamic principles provide the basis for relations among atmospheric pressure, temperature, and density (ideal gas law), as well as the transfer and conversion of energy (first law of thermodynamics). A primary focus of agricultural meteorology is the balance of energy (conservation of energy) for the system being studied, such as a metabolizing organism or a plant-covered or soil surface. For an organism, we can describe the steady state-heat balance by eqn [2].

$$R_n + M = C + LE + G \quad [2]$$

In eqn [2], R_n is the net gain of heat from radiation; M is the net gain of heat from metabolism; C is the loss of sensible heat to air by convection; LE is the loss of latent heat by evaporation of water; and G is the loss of heat to ground and vegetation by conduction. E is the evaporation rate (flux of water vapor per unit area) and L is the latent heat of vaporization. All quantities are considered to be averaged values per unit area. For applications to animal agriculture, M is likely to be a significant factor, but for a soil or vegetated surface, the metabolism contribution is negligible. The radiant component of energy consists of absorbed incoming shortwave energy less net emitted longwave energy.

A plant canopy uses a portion of the shortwave component of this net incoming radiant energy for photosynthesis. In a balanced condition, the plant uses its evapotranspiration capacity to regulate its temperature by converting excess sensible heat to latent heat. Most agricultural animals, like humans, also have the capacity to rid themselves of excess heat by means of evaporation.

Surface Aerodynamics

The aerodynamics of plant interactions with the atmosphere provides a basis for understanding how plants exchange moisture, trace gases, and heat energy with and extract momentum from the free atmosphere through turbulent processes. Descriptions of the movement of pollen, spores, insects, and chemical sprays also require information about mean and turbulent flow processes on scales of centimeters to hundreds of kilometers.

Simple representations of atmosphere-surface interactions are given by drag coefficient formulations of vertical fluxes of quantity S from a surface as given in eqn [3].

$$F_s = -U_t(S_t - S_{\text{surf}}) \quad [3]$$

U_t is the transport velocity for the interface and the values of S are taken at height t and at the surface. The transport velocity at the Earth's surface is usually parameterized by use of a drag coefficient (C_{Ds}) for the quantity S and the mean wind speed at some level (usually taken to be 10 m), i.e., $\{V_{10}\}$ (eqn [4]).

$$U_t = C_{Ds}\{V_{10}\} \quad [4]$$

Drag coefficients depend on atmospheric stability but are typically in the range 1×10^{-3} to 5×10^{-3} (dimensionless).

Concepts of gradient or Fickian diffusion have been used to describe fluxes by measuring vertical gradients and using assumptions or additional measurements to estimate transfer coefficients. Under this approach, the turbulent flux of a quantity is proportional to the vertical gradient of its mean quantities above the surface, eqn [5].

$$F_s = -K_s \frac{\partial s}{\partial z} \quad [5]$$

where K_s is the turbulent diffusion transfer coefficient for variable s , usually estimated to be ku_*z (k being von Karman's constant (0.4) and u_* being the friction velocity) with an additional stability correction factor and constant for each variable s . Equation [5] with an assumed form of K_s is used to derive vertical profiles of temperature and horizontal wind speed over homogeneous surfaces. Profiles inside crop

canopies are more complicated and are usually specified by empirical relations.

Evaporation and Precipitation

Agriculture is practiced over large regions of the Earth where water excess or water deficit is a major limitation for successful crops. Therefore, a major focus of agricultural meteorology and climatology is the study of precipitation and evaporation. The heat balance equation can be used to provide an estimate of the evaporation rate for a surface from knowledge of other components of the heat budget by a type of Penman–Monteith equation (eqn [6]).

$$LE = \frac{\Delta(R_n - H_G) + F_W}{\Delta + \gamma} \quad [6]$$

In eqn [6], $\Delta = RH_s \partial q_s / \partial T$, where RH_s is the saturation relative humidity and q_s is the saturation specific humidity; H_G is the soil heat flux; $F_W = C_E \beta (RH_p - RH_a)$, where C_E is the bulk transfer coefficient for moisture, $\beta = u_* / C_D$, RH_p is the relative humidity at the plant or soil surface, RH_a is the ambient relative humidity, u_* is the friction velocity, and C_D is the drag coefficient; and $\gamma = c_p / L$, where c_p is the specific heat capacity of air at constant pressure. In some implementations, Δ and F_W are replaced by factors that include canopy and atmospheric resistances to flow of heat and momentum.

Both amount and timeliness of precipitation and evaporation are of critical importance to agriculture. Irrigation scheduling requires reliable climate information as well as good weather forecasts, particularly with increased competition for fresh water due to increased population and expanded uses of water. Food security exacerbates the vulnerability of many precipitation-deficient developing countries to interannual variability of precipitation and raises the urgency of improved seasonal to interannual forecasts of weather and climate.

Instrumentation, Measurements, and Networks

Agricultural climatology relies on records of basic meteorological measurements having been taken over extensive areas and significantly long periods of time. These records form the basis for understanding climate variability and change and also for extracting statistically significant relationships between meteorological variables and soil and plant processes, plant, animal, and pest development, and seasonal yield. In addition to standard atmospheric measurements, agriculturists need measurements of soil temperature and soil moisture. These measurements are less widely recorded although they (especially soil moisture) are being recognized for their role in climate memory and hence seasonal forecasting. More such measurements and networks for measurements are needed, particularly in developing countries where use of technology to reduce vulnerability to climate variability is severely limited.

The central role of the surface energy balance in agricultural meteorology calls for accurate methods of evaluating fluxes of heat, momentum, moisture, and trace gases from crop, soil, and forest surfaces. Unfortunately, this is not an easy task for

heterogeneous surfaces typically encountered in agricultural applications. Estimates of surface fluxes can be made by drag coefficient formulations and gradient diffusion estimates or by eddy correlation methods.

The most direct measurement of vertical fluxes is accomplished by using eddy correlation methods, which have seen increased use due to wider availability of improvements in sensors and recording and in data archiving equipment and methods. Eddy correlation methods are based on the principle that turbulent flow near the Earth's surface can lead to vertical fluxes of heat, moisture, momentum, or trace gases in the absence of a mean vertical flux of dry air. We express the vertical flux of quantity s as $F_s = c_s \rho w(t)s(t)$, with a time-averaged value given by $\{F_s\} = c_s \rho \{w(t)s(t)\}$, where c_s is a constant for the particular quantity being transported, ρ is the dry air density, and w is the vertical wind speed. We can express w as a sum of a time-independent mean and a time-dependent turbulent component, $w(t) = w_0 + w'(t)$, and similarly for s , $s(t) = s_0 + s'(t)$. We can then write eqn [7]:

$$\begin{aligned} F_s &= c_s \rho (w_0 + w'(t))(s_0 + s'(t)) \\ &= c_s \rho [w_0 s_0 + w_0 s'(t) + w'(t)s_0 + w'(t)s'(t)] \end{aligned} \quad [7]$$

After time averaging, this becomes eqn [8].

$$\begin{aligned} \{F_s\} &= c_s \rho \{w_0 s_0\} + c_s \rho \{w_0 s'(t)\} + c_s \rho \{w'(t)s_0\} \\ &\quad + c_s \rho \{w'(t)s'(t)\} \end{aligned} \quad [8]$$

The first two terms on the right-hand side of eqn [8] are zero because the mean vertical wind speed is zero. The third term vanishes because, by definition, the mean fluctuation of the vertical wind is zero. The last term can be nonzero, however, if the fluctuation of the vertical wind has correlation other than zero with the fluctuating part of s . The time-averaged turbulent flux of s then reduces to $\{F_s\}$ given by eqn [9], which can be computed by combining measured w' and s' taken from simultaneous recordings of fast response measurements of $w(t)$ and $s(t)$.

$$\{F_s\} = c_s \rho \{w'(t)s'(t)\} \quad [9]$$

The Bowen ratio is defined as the ratio of heat flux to moisture flux near the surface (eqn [10]).

$$B = \frac{C}{LE} = \frac{c_p \{w'T'\}}{L \{w'q'_s\}} \quad [10]$$

From eqn [2], ignoring metabolic contributions, we can express the sensible heat flux and latent heat flux, respectively, from the surface as in eqns [11] and [12].

$$C = \frac{B(R_n - G)}{1 + B} \quad [11]$$

$$LE = \frac{R_n - G}{1 + B} \quad [12]$$

Flux measurements by the eddy correlation method present challenges that can lead to uncertainty of 5–30%. For a particular situation being sampled, an appropriate averaging time must be selected to be long enough to ensure a sufficiently large sample but not so long as to mix turbulent processes with phenomena of longer time scales. Perhaps a more serious problem is the 'representativeness' issue: Fluxes at a point over

an agricultural field are not completely vertical, particularly where inhomogeneities exist in the field. It can be difficult to specify the 'surface footprint' from which the surface flux emerged for situations having changing wind directions, terrain irregularities, changing levels of atmospheric stability, or inhomogeneities of surface vegetation, soil moisture, or soil type. Yearlong measurements of CO₂ flux over a mixed-species forest in irregular terrain, for instance, would require considerably more care in interpretation than daytime measurements over a flat field of corn. Despite the additional expense and care needed in conducting measurements and additional effort for analysis, eddy correlation measurements are increasingly being used for evaluating surface fluxes of CO₂ and other trace gases and moisture.

Measurement networks have been established by some local, state, federal, and international agencies to provide both an expanding climate database and a basis for near-term and seasonal agricultural decision making. There is an urgent need to expand these networks to meet the increasing food needs, particularly in developing countries. A US national measurement network of soil moisture and temperature, as recommended by a National Academies of Science report, would benefit both production agriculture and climate science through improvement in seasonal weather forecasts. Remote sensing by satellite is finding expanded use in providing large-scale data of relevance to agriculture, but its use for individual farmers is limited.

Modeling and Theory

Modeling of plant interactions with the atmosphere has emerged from at least two directions: global climate modelers seeking more accurate representation of energy, momentum, and moisture budgets at the Earth's surface and crop modelers seeking ways of understanding plant responses to climate and of projecting yields of agricultural crops. Climate modelers use the so-called soil-vegetation-atmosphere transfer (SVAT) models as 'surface packages' to which they supply meteorological data at each surface grid point at each model time step (a few minutes to hours). The SVAT model then calculates the response of the soil and plants (e.g., evaporation or transpiration, temperature change, soil moisture content, moisture uptake by roots, rain or dew held on leaves, precipitation runoff, and momentum extracted) and returns to the climate model the surface fluxes of heat, moisture, and momentum consistent with these soil- and plant-based changes. Computational constraints limit the detail to which plant processes can be described, but, as simplistic as they are, the models provide a conceptual framework for eventual coupling of more detailed crop, forest, and ecosystem models.

Crop models may be physiologically based or statistically based. Crop growth models are built on plant biophysical processes of agricultural crops and their relationship to environmental factors. They predict growth, development, and yield based on complex interactions between weather, soil characteristics, nutrients, and plants. A practical application of crop growth models is to estimate agricultural production as a function of weather and soil conditions under alternative management conditions. Basic meteorological information

needed to drive these models includes air temperature, precipitation, and solar radiation (or sunshine hours). More advanced models might additionally use dew-point temperature, wind speed, and soil temperature. Statistically based crop models provide large-area yield predictions based on correlations of past yields with regional average weather conditions. These models tend to be much less computationally intensive but also more location specific and hence less transferable to other regions.

The fate of fugitive agricultural chemicals and movement of insects and pollen are addressed by models of atmospheric flow on scales of turbulent eddies to mesoscale meteorology. Large-eddy simulation models and models developed for use in air pollution regulation are sometimes adapted for simulating transport of agriculturally related materials. Recent advances in numerical simulation of turbulent flow through vegetation have been used to understand the aerodynamic functioning of agricultural shelterbelts. Extensions of these models to simulate the complete microclimate provide opportunities for exploring, by use of first principles, complex physical relationships in heterogeneous ecosystems and landscapes.

Concern for national and international food securities has prompted the need for models of seasonal yield of various food crops. Private organizations as well as governmental agencies have developed yield models based on long-range weather conditions. The Food and Agriculture Organization of the United Nations has developed agrometeorological models that forecast yield on the basis of cumulative weekly or 10-day crop water balances for providing early warning of potential food security problems in developing countries. The Agricultural Model Intercomparison and Improvement Project (AgMIP) is an international effort to improve and couple crop and economic models with the next generation of climate impact projections for improved assessment of food security.

Manipulating Microclimates to Enhance Productivity and Reduce Risk

Agriculturists have a long history of enhancing crop growth by manipulating soil and plant microclimates, through use of irrigation, glasshouses, shelterbelts and windbreaks, snow fences, wind machines, surface mulches, certain tillage practices, alley cropping, and agroforestry. The design and operation of such modifications require considerable information on the mean, extremes, and interannual variability of climate at the specific location where the practice is implemented.

Horticulture crops, which typically have a higher value per unit area than grain crops, are sensitive to small changes in microclimate. Also in contrast to grains, horticulture crops are more sensitive to weather-induced reduction in product quality or market value. For instance, the desirable red coloration on some fruits is sensitive to optimal amounts of solar radiation at a critical stage. Manipulation of microclimates for horticultural crops is more cost-effective than for cereals because of both their high value and their sensitivity of quality to microclimate. Weather extremes may have multiyear impacts on agricultural crops grown as perennials (e.g., fruits, nuts, and grapes), which raises the cost-effectiveness of microclimate modifications for reducing such extremes.

Agriculture Meteorology Forecasts

Agriculturists can use weather forecasts with valid times of a few minutes to several months. Weather forecasts are used for planning tillage and planting operations, seed purchase, chemical application, frost suppression, grain harvesting, transport and storage, pest and disease management, and marketing, as well as crop growth calculations and long-range planning.

Major improvements over the past 10 years in our understanding of the El Niño/Southern Oscillation (ENSO)-related phenomena have enhanced prospects for seasonal to interannual forecasts of agriculture-sensitive climate information. Such information now is being used in early warning systems for planning, management, and operations in some tropical areas. In regions where the climate correlation with ENSO is strong, projected ENSO factors have been used to create projections of stress indices. Current research on this and related areas may offer future progress in seasonal to interannual forecasts.

Climate Data

Agricultural climatologists use long-term records of standard meteorological data to compute derived agriculturally related variables such as growing degree days, heat stress units, frost-free days, Palmer drought index, and temperature–humidity index. These variables have been developed from physiological concepts to correlate with crop development stage, crop yield, weight gain in meat animals, daily milk production, or other agriculturally important parameters.

Education and Training

Basic education for agricultural meteorologists is usually acquired by supplementing a conventional meteorology, physics, or environmental science curriculum with courses on plant, soil, or animal science, forestry, or horticulture. Only a few US and European universities offer undergraduate or graduate degrees specifically in agricultural meteorology. Most courses of study with emphasis in agricultural meteorology are connected with more traditional programs in agriculture such as agronomy. India has taken a more coordinated approach than almost any other country to the university education of agricultural meteorologists. Increased needs in the developing world have expanded the definition of agricultural meteorology to include more frequent weather and climate disasters that threaten production systems. The World Meteorological Organization recently and in applications to developing countries has cited the socioeconomic aspects such as irrigation, storage, agroforestry, floods, drought, erosion and desertification, frost, wind protection, simple artificial growth conditions, sustainable farming, and related farmers' income as emerging priorities in agricultural meteorology.

The practical applications of agricultural meteorology have created needs for training programs aimed at changing the knowledge, skills, and behavior of personnel to achieve the objectives of the organizations they work for. The World Meteorological Organization provides in-service training

through regional meteorological training centers that offer specialized courses in basic agricultural meteorology, database management, agricultural meteorology modeling, and hydro-meteorology. These short courses tend to be task oriented, focusing on improving and standardizing the practice of agricultural meteorology, particularly in relation to observations and data management.

Rapid advances in the field of meteorology have increased the need for more lifelong learning opportunities both in basic education and in training. Increased interest in global observing networks for monitoring a wider range of environmental variables exacerbates this need. The Internet offers a potential means of delivering standardized and authoritative educational and training materials to larger fractions of the global agricultural meteorology community.

Future Issues

The potential impact of global climate change on agriculture has been a subject of intense study in recent years. Uncertainties in projections of future climates at regional scales limit the accuracy with which agricultural impacts can be estimated. However, there is high confidence that increases in atmospheric carbon dioxide will have a beneficial effect on crops both through direct fertilization and through increased water use efficiency. The mean yield increase for C_4 crops (e.g., maize, sugar cane, millet, and sorghum) under a doubling of atmospheric CO_2 is minimal, whereas increases for C_3 crops (most other plants) may be up to 30%, other factors being equal. Loss of soil organic matter, leaching of soil nutrients, and salinization and erosion of soils will occur in some climatic zones, which will call for more effective agricultural land use practices. Crop yields and productivity will vary considerably across different climate zones under climate change, with low-latitude and low-income countries being most negatively affected and some high-latitude countries experiencing more favorable crop growing conditions than under the current climate.

Advances in our knowledge in the traditional areas of agricultural meteorology – surface fluxes of energy, moisture, and trace gases and the study of precipitation and evaporation processes – will be urgently needed for coping with interannual variability and long-term change of future climates. And practical applications of this new knowledge require timely, efficient, and worldwide distribution networks. Emergence of social media fostered widespread use of cell phones and internet provides rich opportunities for democratizing the dissemination of time-sensitive weather and climate information for agricultural decision making.

Better understanding of basic agricultural micrometeorology and associated plant and soil processes will allow for continuing advances in applied agricultural meteorology as well as at larger scales of meteorology. Measurements of heterogeneities in soil and microclimate across a field are increasingly being used for site-specific management of plant environments and yield improvement. At larger scales, the subtle processes regulating the exchange of moisture and energy of plants and soil with the atmosphere are key to improvements in numerical models of mesoscale meteorology and global climate.

Synopsis

Very different climatic regimes are found across the Antarctic, from dry, very cold conditions with few depressions over the interior plateau, to windy and wet maritime environments toward the tip of the Antarctic Peninsula. Although well removed from the other continents, the climate of Antarctica is affected by conditions across the other parts of the Earth, and especially the ocean temperatures in the tropical Pacific Ocean. The climate of the Antarctic has a large interannual variability as a result of interactions between the atmosphere, ocean, and ice. Over the last 50 years the Antarctic Peninsula has experienced a surface warming as large as any in the Southern Hemisphere. This warming extends into West Antarctica, but the rest of the continent has experienced little change. The loss of stratospheric ozone (the ozone hole) has had a major impact on the climate of the Southern Ocean, increasing the surface winds by about 15%. The ozone hole is expected to recover by 2060–2070, but if greenhouse gas concentrations continue to rise there will be a surface warming of several degrees across Antarctica, more precipitation, and a loss of sea ice.

Introduction

Antarctica is the highest, coldest, windiest, and driest continent on Earth, with a climate that varies from extremely cold and dry on the high plateau of East Antarctica to maritime across the northern part of the Antarctic Peninsula. Although remote from the major centers of population, it plays a crucial role in the global climate system and is closely coupled to conditions at lower latitudes via the oceanic and atmospheric circulations.

The Antarctic continent is about 40% larger than the United States, covering an area of $14 \times 10^6 \text{ km}^2$, which is about 10% of the land surface of the Earth. The Antarctic ice sheet contains about $30 \times 10^6 \text{ km}^3$ of ice or about 70% of the world's fresh water, which is equivalent to about 60 m of sea level. The ice sheet is made up of three distinct zones, consisting of East Antarctica (covering an area of $10.35 \times 10^6 \text{ km}^2$), West Antarctica ($1.97 \times 10^6 \text{ km}^2$), and the Antarctic Peninsula ($0.52 \times 10^6 \text{ km}^2$) (Figure 1).

The orography of the continent has a profound effect on the climate of high southern latitudes, limiting the extent to which depressions can penetrate into the interior and giving rise to the katabatic (downslope) winds that are a major feature of the coastal zone. The elevation of the ice surface rises very rapidly inland from the coast, and the continent has a domed profile,

with much of it being above 2000 m in elevation and some parts over 4000 m.

The other landmasses of the Southern Hemisphere are well north of the Antarctic, so that the oceanic and atmospheric flow is much more zonal than in the Northern Hemisphere. However, the highest parts of the ice sheet are found in East Antarctica and are slightly offset from the South Pole, which has implications for the atmospheric circulation around the continent.

The Broad-Scale Synoptic Environment

The Antarctic coastal region is a zone of strong, horizontal thermal gradients (baroclinicity) where cold katabatic winds flow off the continent and meet temperate, maritime air, resulting in the development of many depressions (cyclogenesis). It is also the area where many depressions spiraling south from midlatitudes become slow moving and decline (cyclolysis). The depressions carry warm (cold) air southward (northward) on their eastern (western) flanks and play an important part in the poleward transport of heat.

The large number of depressions in the 60–70° S zone results in a low-pressure belt around the continent known as

Figure 1 A map of the Antarctic showing regions, topographic features, and the locations of selected research stations.

the circumpolar trough, which is apparent on the mean sea level pressure (MSLP) (**Figure 2**). Within the trough, depressions mainly move toward the east, with the clockwise flow around these systems giving a climatological easterly wind along the Antarctic coast and westerly winds north of the trough.

The circumpolar trough is present throughout the year, and in the mean fields it has an approximate wave number 3 pattern with low-pressure centers close to 30° E, 90° E, and 150° W. This pattern affects a number of aspects of the Antarctic climate, such as the northward extension of sea ice close to the Greenwich meridian, as a result of the climatological southerly flow at this longitude. Because of the distribution of land-masses in the Southern Hemisphere, the atmospheric planetary

waves have a smaller amplitude than their counterparts in the north, so the depressions play a greater role in the poleward transport of heat than in the Northern Hemisphere.

The most marked climatological low-pressure center around the continent is at 150° W and is often referred to as the Amundsen Sea Low. The presence of this low is responsible for the north-to-northwesterly flow on the western side of the Antarctic Peninsula and the relatively mild temperatures that are experienced there. It also gives a mean southerly flow off the Ross Ice Shelf and over the Ross Sea, resulting in this area being a major sea ice production region.

Figure 2 shows that MSLP values within the circumpolar trough are lowest during the spring and autumn and are higher during the summer and winter. This semiannual

Figure 2 Average mean sea level pressure (hPa) for the four seasons for the period 1979–2010: (a) spring (September–November), (b) summer (December–February), (c) autumn (March–May), and (d) winter (June–August).

oscillation can be seen in the MSLP observations from the coastal stations and also in the number of reports of precipitation. The oscillation is a result of changes in the position and depth of the circumpolar trough over the year, with it being further south (north) and deeper (weaker) in autumn and spring (summer and winter). The oscillation is present because of the phase differences between the seasonal cycles of temperature over the Antarctic continent and Southern Ocean. Across the Antarctic, temperatures drop very rapidly at the start of winter, while over the ocean the minimum is in late winter and early spring. This results in the movement of mass between high latitudes and midlatitudes, giving rise to the semiannual oscillation.

Satellite imagery has revealed that over the Southern Ocean, there are a large number of mesoscale low-pressure systems, which are also known as mesocyclones or polar lows. These have a horizontal length scale of less than 1000 km and a life-time of less than 1 day, so they are difficult to represent and forecast in numerical weather prediction systems. However, they can have a major impact on the weather experienced at coastal sites and so are important in forecasting processes. At the moment, they tend to be predicted using a 'nowcasting' approach, with the systems being identified on satellite imagery and advected with the low- to medium-level tropospheric flow. Although mesocyclones are rare over the high Antarctic Plateau, they are a common feature on the ice shelves. Here,

there is low-level convergence of air that has descended from the plateau, which aids the spin-up of vortices, coupled with the presence of mild, oceanic air masses that provide moisture for cloud formation.

Because of the rapid increase in elevation inland of the coast, few major weather systems penetrate far into the interior of the continent. However, satellite imagery does show that some frontal bands associated with depressions in the circumpolar trough can be identified on the plateau, although automatic weather station data suggest that the pressure signals across these features are small. The conditions that favor depressions having an impact in the interior are amplified planetary waves and strong northerly steering flow aloft. Under such conditions, mild air masses over the plateau can give relatively large falls of precipitation, resulting in a significant fraction of the year's accumulation falling in 1 or 2 days. When the planetary waves are strongly amplified, maritime air masses can affect the South Pole and even Vostok Station on the high plateau of East Antarctica, but such conditions are rather rare.

The Role of Sea Ice

The presence and extent of sea ice across the Southern Ocean have a major impact on the climate of the Antarctic. Unlike in the Arctic, most of the sea ice melts by the late summer, so by February there is on average only about 3.5×10^6 km² of ice, most of which is located over the western Weddell Sea and along the coast of West Antarctica. Through the autumn and winter, the sea ice advances in a divergent fashion around the whole continent, reaching a maximum in September, when the mean extent is about 19×10^6 km².

The Antarctic sea ice is generally about 1 m thick, with some multiyear ice being 2 m or more in thickness where it has been subject to ridging and rafting. The ice provides an effective cap on the upper layers of the ocean, limiting the fluxes of heat and moisture into the lower layers of the atmosphere. However, the effects of the many weather systems over the Southern Ocean on the sea ice is to open up linear cracks (leads) or larger areas of open water (polynyas), which can provide local sources of heat or moisture, resulting in cloud. This can be important for the climates of the coastal stations during the winter months when the opening up of coastal leads and polynyas can significantly increase the temperature and humidity, sometimes leading to fog formation.

An area that is particularly sensitive to the presence or absence of sea ice is the western side of the Antarctic Peninsula. Here, the sea ice passes north–south along the coast during its annual cycle, and years of extensive (limited) sea ice are notably colder (warmer).

Temperature

Much of the Antarctic is extremely cold because of the combined effects of the long period of winter darkness; the high albedo of the snow surface, which results in the reflection of much of the summer incoming solar radiation back to space; and the high elevation, which limits the penetration of maritime air masses into the interior. The Antarctic atmosphere is

characterized by a very strong surface temperature inversion, with temperatures increasing with height over the lowest few hundred meters of the atmosphere. The temperature inversion is strongest in winter on the high plateau and is the result of the intense radiative cooling of the surface and the low wind speeds that give little vertical mixing. The mean strength of the winter inversion (i.e., the temperature difference between the surface and the maximum temperature in the lower troposphere) varies from about 5 °C in the coastal region to more than 25 °C over the highest parts of East Antarctica.

Across the Antarctic, there is a very large range of annual mean surface air temperatures, although it is only in the northernmost part of the Antarctic Peninsula that mean summer temperatures rise above freezing. Over the Antarctic Peninsula and along the coast of East Antarctica, the annual cycle of temperature is similar to those found in midlatitudes, with a broad summer maximum and a minimum in July or August. However, at more southerly latitudes, the cycle is different, with a sharp summer maximum and a 'coreless' winter, during which temperatures vary by only a small amount. This form of the annual cycle comes about for a number of reasons, including the abrupt change in solar radiation at the start and end of the period of austral darkness, the effects of the semiannual oscillation on the annual cycle of advection of warm air into the Antarctic, and the heat reservoir effect of the Antarctic snow pack.

The plateau of East Antarctica experiences the lowest temperatures on Earth, with Vostok Station (78.5° S, 106.9° E, 3488 m elevation) having an annual mean temperature of −55.4 °C. The station has recorded the lowest temperature measured at the surface of the Earth, when on 21 July 1983 the temperature dropped to −89.6 °C. This occurred during a period when there was very little cloud, the wind speed was very low, and the winds blew around the station, limiting the advection of warmer maritime air. A station has recently been established at Dome Argus at an elevation of 4083 m above sea level, and early observations suggest that it is typically 5–6 °C colder than Vostok. It therefore has the potential to record an even lower extreme surface temperature than Vostok.

At higher levels in the troposphere the Antarctic atmosphere is strongly stratified, much more so than in the midlatitude areas of the Southern Hemisphere. This is the case in all seasons, with the stability being strongest below about 4 km during the winter. Temperature data from radiosonde ascents usually show a tropopause in summer, but it can become very indistinct during the winter when the stratosphere cools rapidly.

The Wind Field

The strong, persistent, and directionally constant near-surface winds recorded at a number of sites around the Antarctic are one of the most remarkable features of the continent's climate. Many of the winds at stations around the coast of East Antarctica are katabatic in origin and occur because of the drainage of cold, dense air at low levels from the interior plateau to the coast. [Figure 3](#) shows the near-surface streamlines across the continent derived from the output of a high-resolution weather-forecasting model. These show that much of the flow originates in the higher parts of East Antarctica and flows

Figure 3 Near-surface mean streamlines for the period June 2003–May 2004 from the Antarctic Mesoscale Prediction System. Reproduced from Parish, T.R., Bromwich, D.H., 2007. Reexamination of the near-surface airflow over the Antarctic continent and implications on atmospheric circulations at high southern latitudes. *Monthly Weather Review* 135, 1961–1973. Used by permission of the American Meteorological Society.

toward the coast, often converging toward certain preferred coastal locations. The katabatic winds are most pronounced during winter, when there is no incoming solar radiation, and a large pool of cold air over the interior is formed to feed the katabatic flow.

Surface winds over the interior show a high directional constancy, indicating that they are dictated by the local orography. The wind speeds are closely related to the slope of the orography, with the strongest winds being measured at stations on the coastal escarpment and the weakest on the parts of the plateau with the smallest orographic gradient. Along the coast of Adélie Land, the orography channels the katabatic flow onto a small stretch of coast, resulting in very strong and persistent winds with a very high directional constancy. It was in this area that Douglas Mawson's 1912–13 expedition recorded the Earth's highest annual mean wind speed of 19.4 m s^{-1} and gale-force winds on all but one of 203 consecutive winter days.

As the katabatic winds descend from the plateau, they interact with the synoptic-scale weather systems within the circumpolar trough. The northerly winds to the east of the lows

tend to suppress the southerly katabatic flow, while the katabatics are enhanced by the southerly flow to the west of the depressions. The Coriolis force also affects the katabatic winds, tending to turn them to the left so that they merge with the coastal easterlies on the southern side of the circumpolar trough. The near-surface flow therefore appears as an anticyclonic vortex, with cold air outflow from the continent. In some parts of the coastal region, such as south of the Weddell Sea, the coastal easterly flow comes up against high orography, and the cold, stably stratified air at low levels does not have the kinetic energy to cross the barrier. The air is then dammed up against the barrier until a pressure gradient develops that results in the air moving north as a 'barrier wind.' With the strong static stability encountered at low levels in the Antarctic, barrier winds are relatively common in the coastal areas of the continent.

Clouds and Precipitation

Clouds are very important in the Earth's climate system as they can reflect a high proportion of incoming solar radiation back

to space. However, since the surface of the Antarctic already has a high albedo by virtue of its year-round snow cover, clouds over the continent tend to have less of an effect on the incoming solar radiation because the surface and cloud have similar albedos. Nevertheless, clouds play a very important part in controlling surface temperatures through their effect on the long-wave radiation budget. In cloud-free conditions, the dry atmosphere allows most of the emitted terrestrial radiation to escape to space, resulting in very low temperatures. However, when thick cloud cover is present, surface temperatures are much higher because of the downward long-wave radiation emitted from the cloud.

Since most of the research stations are located in the coastal region, it is difficult to get an accurate picture of the cloud distribution across the continent. However, using in situ data and satellite imagery, climatologies of cloud cover have been prepared. These suggest that the highest fractional cloud cover is found over the ocean areas north of the edge of the continent, with about 85% cloud cover throughout the year near 60° S. In

the coastal area near 70° S, the surface observations indicate that the total cloud cover is about 45–50%, with little seasonal variability and only a small decrease during the winter months. Inland of the coast, the amounts of thick cloud decrease rapidly, since few synoptic-scale weather systems are found over the interior. However, the inland areas are characterized by extensive, very thin cirrus cloud, which gives a semipermanent veil of ice crystals. This type of cloud causes problems for observers, who have to decide whether to report no cloud or 100% cloud cover. The mean annual percentage cloud cover at the South Pole is 45%, but anyone using such statistics has to be aware of the nature of the cloud that occurs there and the problems facing observers of how to report the thin cirrus.

The amount of precipitation across the Antarctic generally follows the distribution of thick cloud. In other words, the highest precipitation totals are found in the coastal region, with a rapid decrease inland. **Figure 4** shows the mean annual net accumulation (precipitation–evaporation) across the continent as estimated from ice cores. These glaciological

Figure 4 An estimate of snow accumulation across the Antarctic based on ice core data. Isopleths are in units of $100 \text{ kg m}^{-2} \text{ year}^{-1}$ (or, equivalently, 100 mm year^{-1}). Reproduced with permission from Bromwich, D.H., 1988. Snowfall in high southern latitudes. *Reviews in Geophysics* 26, 149–168. © American Geophysical Union.

measurements of accumulation are very similar in magnitude to those of precipitation, since there is little evaporation in the interior. However, they are not identical, because of the effects of blowing snow and summer melt in some areas. But with so few in situ measurements of precipitation, they have been used extensively as a proxy for precipitation. In Figure 4, it can be seen that no data are presented for the northern part of the Antarctic Peninsula because precipitation varies so rapidly in this area. The area of greatest precipitation is along the coast of the southern Bellingshausen Sea, where there is over 1 m water equivalent per year. This peak is found because of the high frequency of northerly airstreams bringing mild, moist air onto the coast. Other areas of high precipitation are found where there is frequent cyclonic activity, such as north of Enderby Land and along the coast of East Antarctica. Some of the smallest amounts of accumulation are found on the low-lying Ross and Ronne Ice Shelves. Inland of the coast, the amounts of accumulation drop very rapidly, so over most of East Antarctica there is less than 50 mm of accumulation per year.

A number of estimates have been made of the mean and total snow accumulation across the whole of the Antarctic ice sheet using glaciological data gathered in situ. Studies suggest that the mean accumulation is about 160 mm water equivalent per year, which is equivalent to a total input of approximately 2205 Gt year⁻¹.

The mechanisms behind precipitation are different across the Antarctic, with most precipitation in the coastal area coming from synoptic-scale weather systems. In the interior, most falls in the form of clear-sky precipitation, also known as 'diamond dust.' This is an almost continuous fallout of ice crystals from a thin veil of cirrus cloud covering the sky. Clear-sky precipitation has not been investigated extensively, but is thought to result from the cooling of air over the plateau and the formation of ice crystals as the precipitation descends into the cold near-surface layer. Just inland of the coast, there is a zone where both synoptic-scale weather systems and clear-sky precipitation play a role. Over Queen Maud Land, studies have shown that clear-sky precipitation falls on most days, but that a few major weather systems can give a significant fraction of the year's accumulation in a few days.

Climate Variability and Change

The high-latitude areas exhibit a greater degree of interannual and interdecadal climate variability than locations in the

tropics or midlatitudes. This is a result of the complex interactions between the atmospheric circulation and the cryosphere, including a number of positive-feedback mechanisms that amplify climate variability. However, our understanding of climate variability and change is limited in the Antarctic because of the shortness of the in situ records and the fact that most research stations are on the coast, with only the Vostok and Amundsen-Scott stations providing long records from the interior.

Standard deviations of the annual mean surface air temperatures for a number of stations are given in Table 1. These stations are located in different climatic regimes: at the South Pole (Amundsen-Scott Station), on the high interior plateau (Vostok), on the coast of East Antarctica (Mawson), and on the Antarctic Peninsula (Faraday/Vernadsky and Bellingshausen). Most of the stations have very similar variability of temperature, which is perhaps surprising considering the very different environments in which they are located. Variability of depression activity in the coastal area is to be expected, which would vary the temperatures. However, the figures show that conditions in the interior also vary from year to year as a result of changes in atmospheric circulation. But the station with the largest variability is Faraday/Vernadsky station on the western side of the Antarctic Peninsula. This station is located close to an area of large sea ice extent variability, and small changes in ice extent are amplified into much larger surface temperature variations.

The primary mode of Antarctic climate variability is the southern annular mode (SAM), which consists of synchronous pressure anomalies of opposite signs in midlatitudes and high latitudes. Thus, the SAM can be considered an index of the strength of the midlatitude westerlies. When pressures are below (above) average over Antarctica, the SAM is said to be in its high (low) index or positive (negative) phase. The SAM contributes a significant proportion of Southern Hemisphere climate variability (typically ~35%) from high-frequency to very low-frequency timescales. The SAM shows a high level of intrinsic variability, but is also affected by the amount of volcanic aerosol in the atmosphere, the concentration of greenhouse gases, and the Antarctic 'ozone hole.' The SAM has shown significant positive trends during autumn and summer over the past few decades, resulting in a strengthening of the circumpolar westerlies by about 15%. It has been suggested that the more positive SAM since about 1980 has mainly been a result of the 'ozone hole,' although during the first decade of the twenty-first century, the SAM

Table 1 Mean temperature data for selected Antarctic stations

Station	Latitude	Longitude	Elevation (m)	Period	Mean annual temperature (°C)	Standard deviation of the annual mean temperature (°C)	Mean January temperature (°C)	Mean July temperature (°C)
Vostok	78.5° S	106.9° E	3488	1958–2010	−55.3	0.9	−32.1	−66.8
Amundsen-Scott	90.0° S	—	2800	1957–2010	−49.4	0.7	−28.1	−60.0
Mawson	67.6° S	62.9° S	16	1955–2010	−11.2	0.7	+0.1	−18.0
Faraday/Vernadsky	65.4° S	64.4° W	11	1951–2010	−3.7	1.6	+0.7	−8.7
Bellingshausen	62.2° S	58.9° W	16	1969–2010	−2.3	0.8	+1.5	−6.5

became more neutral at a time when the ozone hole was still showing no clear sign of recovery.

The near-surface air temperature trends since 1951 at selected Antarctic stations are presented in Figure 5. The data show a strong dipole of change, with significant warming across the Antarctic Peninsula but with very small trends across the rest of the continent. The largest warming trends in the annual mean temperatures are found on the western and northern parts of the Antarctic Peninsula. Here,

Faraday/Vernadsky station has experienced the largest statistically significant ($<1\%$ level) trend in annual mean temperature of $+0.54\text{ }^{\circ}\text{C}$ per decade for the period 1950–2009. The rate of warming decreases away from Faraday/Vernadsky, with the long record from Orcadas on Signy Island, South Orkney Islands, having experienced a warming of only $+0.20\text{ }^{\circ}\text{C}$ per decade. However, it should be noted that this record covers a 100-year period rather than the 60 years for Faraday/Vernadsky.

Figure 5 Antarctic near-surface temperature trends for 1951–2009. The scale in the bottom left corner indicates the warming or cooling over the full length of the station records. The numbers above the bars indicate the statistical significance by percentage.

The warming at Faraday/Vernadsky has been largest during the winter, with the temperatures increasing during that season by $+1.03^{\circ}\text{C}$ per decade over 1950–2009. In this area, there is a high anticorrelation during the winter between the sea ice extent and the surface temperatures, suggesting that more sea ice was present during the 1950s and 1960s, with a progressive reduction since that time.

Temperatures on the eastern side of the Antarctic Peninsula have risen most during the summer and autumn months, with Esperanza having experienced a summer increase in annual mean temperature of $+0.42^{\circ}\text{C}$ per decade over 1945–2009. This temperature rise has been linked to a strengthening of the westerlies as the SAM has shifted into a more frequent positive phase. Stronger winds have resulted in more relatively warm, maritime air masses crossing the peninsula and reaching the low-lying ice shelves on the eastern side.

Estimating temperature trends across the remote interior of the Antarctic is difficult because of the lack of staffed stations, and there has been an active debate over how far into West Antarctica the warming observed on the Antarctic Peninsula extends. With no long-term in situ records available, attempts have been made to estimate trends here using data from the coastal stations and knowledge of the spatial pattern of temperature variability. At the moment, it is thought that there has been a small warming across West Antarctic since the 1950s, but the magnitude is smaller than on the Antarctic Peninsula.

The Antarctic radiosonde temperature profiles suggest that there has been a warming of the troposphere and cooling of the stratosphere over the last 30 years, which is the pattern of change that would be expected from increasing greenhouse gas concentrations. However, the midtroposphere has warmed more in winter than anywhere else on Earth at this level. The radiosonde data show that regional midtropospheric temperatures have increased most around the 500 hPa level, with statistically significant changes of $0.5\text{--}0.7^{\circ}\text{C}$ per decade. The exact reason for such a large midtropospheric warming is not known at present. However, it has been suggested that it may, at least in part, be a result of greater amounts of polar stratospheric cloud during the winter.

Possible Future Change

The twenty-first century will be a period when we expect the Antarctic ‘ozone hole’ to recover, and we will possibly see stratospheric ozone levels returning to normal levels by 2060–70, but with greenhouse gas concentrations increasing. The ‘ozone hole’ has in many ways shielded the Antarctic from the impact of greenhouse gas concentration increases, but this will diminish over the coming decades.

Various scenarios of how greenhouse gas concentrations will increase during the twenty-first century have been considered by the Intergovernmental Panel on Climate Change (IPCC), but here we will examine how the Antarctic climate might evolve if CO_2 concentration increases to

720 ppm by 2100, which is one of the most frequently considered scenarios.

With a doubling of CO_2 over the twenty-first century, we expect the SAM to be even more predominantly positive in the future during all four seasons, further increasing the speed of the westerly winds over the Southern Ocean. Although a positive SAM has resulted in little warming around the coast of East Antarctica in recent decades, a doubling of greenhouse gas concentrations would result in a general warming across the continent and Southern Ocean. Estimates from the output of IPCC Fourth Assessment report models suggest that the surface warming averaged over the continent would be of the order of $3\text{--}4^{\circ}\text{C}$, which is approximately the same magnitude as that over other land areas of Earth. However, the models suggest that the largest warming in the Antarctic will be across the high-latitude areas of the Southern Ocean in winter as a result of the loss of sea ice and the greater fluxes of heat into the atmosphere. Here, the models suggest a temperature increase in excess of 0.5°C per decade.

Although the extent of Southern Hemisphere sea ice has increased slightly in recent decades, it is expected to decrease markedly during the coming century. Modeling studies have suggested that the ice extent could decrease by about 25% for the year as a whole, with a loss of around 50% in March and 20% in September.

If temperatures rise across the Antarctic over the next century, the air will be able to hold a greater amount of moisture. Since air masses are advected southward and forced up onto the Antarctic Plateau by depressions over the Southern Ocean, we can expect greater amounts of precipitation, especially in the coastal region. Estimating the increase in precipitation is difficult, but models suggest this could be of the order of 20% by 2100.

Synopsis

Key features of the Arctic, such as its low mean annual air temperature, stable boundary layer, sea ice cover, permafrost, and snow cover, largely result from limited solar radiation receipts as compared to lower latitudes. The high albedo of snow and ice helps to maintain the Arctic in a low thermal energy state. However, regional features of the atmospheric and ocean circulation and surface modify primary latitudinal controls to result in a variety of climate conditions across the Arctic. Recent decades have seen pronounced changes in the Arctic, including reductions in sea ice extent, largest in September, and rises in surface air temperature, largest in autumn and winter.

Physical Features of the Arctic

The Arctic is defined as the region lying north of the Arctic Circle (66.5622° N latitude). In the north of the Arctic Circle, the sun remains above the horizon for 24 h (polar day) at least 1 day per year and below the horizon for 24 h (polar night) at least 1 day per year. On the Arctic Circle those events occur at the June and December solstices, respectively. The North Pole (90° N) experiences 6 months of polar day and 6 months of polar night.

Most of the region north of 70° N is occupied by the Arctic Ocean. Except for the sector straddling the date line between about 20° E and 20° W, the ocean is surrounded by land. Because of its largely landlocked nature, the Arctic Ocean is sometimes referred to as a Mediterranean-type sea. The dominant feature of the ocean surface is its floating sea ice cover. Northern Hemisphere sea ice extent, defined as all areas with an ice concentration (a fractional ice coverage) of at least 15%, waxes and wanes with the seasons (**Figure 1(a) and 1(b)**), typically ranging from upward of 15×10^6 km² in March to 7×10^6 km² or lower in September. These figures include seasonal ice in areas such as the Sea of Okhotsk, the Bering Sea, and Hudson Bay Ice that lie south of the Arctic Circle. The ice cover can be divided into first-year ice that is formed in a single ice growth season, and multiyear ice, which is ice that has survived one or more summer melt seasons. Any first-year ice present at the end of the melt season in September hence gets promoted to multiyear ice. Sea ice thickness ranges widely from a thin veneer to locally over 10 m. The probability distribution of sea ice thickness has a peak of about 3 m. While multiyear ice tends to be thicker than first-year ice, ridging and rafting can result in very thick first-year ice. Because of brine rejection during its formation, sea ice is nearly freshwater. For ice thicker than 1 m, a salinity of 2–6 parts per thousand is typical. Due to subsequent brine drainage by gravity, salinities for multiyear ice are considerably lower.

Apart from areas of land fast ice, the sea ice cover is in near-constant motion. The large-scale mean annual drift pattern is characterized by the clockwise Beaufort Gyre, centered over the Beaufort Sea north of Alaska, and the Transpolar Drift Stream, a motion of ice from the Siberian coast, across the pole and

through Fram Strait (the strait at about 80° N separating Greenland from the Svalbard Archipelago) (**Figure 2**). This pattern reflects roughly equal contributions by winds and surface ocean currents, the latter ultimately wind driven to a large extent. The mean annual sea ice circulation hence broadly resembles the mean annual sea level circulation of the atmosphere. Mean annual drift speed ranges from 1 to 5 cm s⁻¹ in the Beaufort Gyre and tends to increase along the Transpolar Drift Stream and through Fram Strait, where mean values may exceed 10 cm s⁻¹.

Snow cover atop the sea ice cover of the central Arctic Ocean is generally present for 10 months of the year. Most of the surrounding land surface of the Arctic is snow covered from October through May, with the duration of snow cover increasing with latitude. However, precipitation is generally scant in the Arctic. Some of the land, such as in the Canadian Arctic Archipelago, is classified as polar desert, often with less than 5% plant cover. In lower Arctic latitudes, the tundra commonly includes shrub vegetation of birch and willow. Permanent land ice is primarily restricted to the Greenland ice sheet (containing about 7 m of global sea level equivalent) and the ice caps and glaciers of the northeastern Canadian Arctic Archipelago, and the archipelagos of Svalbard, Novaya Zemlya, Severnaya Zemlya, and Franz-Josef Land. However, most Arctic land is underlain by perennially frozen ground (permafrost), overlain by an active layer exhibiting seasonal thaw. Permafrost acts as an impermeable barrier. As a result, many areas are covered by shallow thaw lakes in summer.

Atmospheric Circulation

Large-Scale Features

The primary feature of the northern high-latitude mid-tropospheric circulation is the polar vortex. The vortex is strongly asymmetric during winter (**Figure 3(a)**) with major troughs over eastern North America and eastern Eurasia and a weaker trough over western Eurasia (the Urals trough). A strong ridge is located over western North America. The lowest tropospheric pressure heights in winter are located over northern Canada. These features are related to orography, land-ocean distribution, and

Figure 1 Arctic sea ice concentration for (a) 15 March 2010 and (b) 15 September 2010 based on data from the Advanced Microwave Sounding Radiometer (AMSR-E) aboard the NASA Aqua satellite (University of Bremen, Bremen, Germany).

radiative forcing. The polar vortex is much weaker during summer and is more symmetric than its winter counterpart, with the lowest pressure heights centered roughly over the pole (Figure 3(b)). This shift of the vortex core to over the pole is consistent with the presence of a melting sea ice cover, which strongly inhibits heating of the overlying atmosphere.

The mean annual sea level pressure field (Figure 2) masks large seasonal variability. The dominant sea level features of the mean winter circulation (Figure 4(a)) are the Icelandic Low off the southeast coast of Greenland, the Aleutian Low in the north Pacific basin, and the Siberian High over central Eurasia. In comparison to Figure 2, note the absence of a closed anticyclone over the Beaufort Sea; in winter the region is instead part of a saddle of high pressure extending from the Siberian High across the ocean and into northwestern Canada. The Beaufort Sea high is actually best expressed during spring. The Icelandic and Aleutian Lows are maintained by low-level thermal effects of the comparatively warm and largely ice-free underlying ocean, and position downstream of the major mid-tropospheric stationary troughs where eddy activity is favored. Regional cyclone development processes are also prominent in the vicinity of the Icelandic Low (see

Extratropical Cyclone Activity and Polar Lows). The Siberian High is a cold, shallow feature. The Icelandic and Aleutian Lows are much weaker during summer as compared to winter (Figure 4(b)). Summer also sees replacement of the Siberian High by mean low pressure, related in part to strong seasonal heating of the land surface. A weak high-pressure cell is found in the southern Beaufort Sea. An area of mean low pressure is also found centered near the pole.

Extratropical Cyclone Activity and Polar Lows

Winter cyclone activity is most prominent over the Atlantic side of the Arctic (Figure 5(a)). Atlantic-side cyclones typically take a northerly to easterly track and collectively represent part of the North Atlantic cyclone track. Activity peaks in the vicinity of the Icelandic Low. Cyclone development is favored because of temperature contrasts between the warm, northward flowing North Atlantic drift current and the cold, southward flowing East Greenland current, proximity to strong horizontal temperature gradients along the sea ice margin (see Figure 1(a)), and distortions to the atmospheric flow induced by the topography of the Greenland ice sheet. Synoptic events in the vicinity of the

Figure 2 Mean annual sea ice drift (cm s^{-1}), based on data from drifting buoys, manned and unmanned camps and mean annual sea level pressure (hPa, see color scale). Reproduced from Serreze, M.C., Barrett, A.P., 2011. Characteristics of the Beaufort Sea high. *Journal of Climate* 24, 159–182.

Iceland Low include splitting (bifurcation) of cyclones at the southern tip of Greenland, with one center tracking northward along the west side of Greenland and the other tracking east of Greenland, orographic cyclogenesis in the lee of Greenland, and rapid deepening of existing systems that have migrated into the region from the south.

The North Atlantic cyclone track is weaker in summer, but cyclone activity increases over land (**Figure 5(b)**). Summer cyclogenesis is favored over northern Eurasia and over Alaska and extending southeast. A summer cyclone maximum is also found over the central Arctic Ocean, centered near the North Pole in the long-term mean. The summer cyclone pattern is associated with the influx of lows generated over the Eurasian continent and cyclogenesis over the Arctic Ocean itself. Systems entering the central Arctic Ocean from the outside, or formed within the region, migrate around the 500 hPa polar vortex, and decay within the cyclone maximum region or in close proximity. These processes help to maintain the weak

mean low-pressure cell centered near the pole seen in **Figure 4(b)**.

Polar Lows are cold season mesoscale systems that form within or at the leading edge of polar air streams. Polar Lows are particularly common in the Nordic Seas, the Labrador Sea, the Bering Sea, the Gulf of Alaska, and the Sea of Japan. Polar Lows are typically less than 500 km in diameter. They may intensify rapidly and surface wind speeds can reach hurricane force, but they also tend to be short-lived, existing 3–36 h. When moving over land or the sea ice cover, they tend to rapidly dissipate. They can be thought of as hybrid systems, typically having features of both baroclinic and convective in nature. A common feature of Polar Lows seen in satellite imagery is a spiral cloud (comma cloud) signature. Some systems develop a clear eye at the center similar to tropical cyclones. Rapid intensification of an intense Polar Low seems to require some element of convection. Preferred areas for Polar Low development mentioned above are those that are

Figure 3 Mean 500 hPa height fields (m) for (a) January and (b) July based on NCEP/NCAR reanalysis data for the period 1970–99.

commonly subject to cold polar outbreaks, where cold continental air is advected over relatively warm open water – conditions favoring convection. This helps explain why Polar Lows are essentially cold season phenomena.

Frontal Activity

The concept of preferred geographical regions of frontal activity in northern high latitudes distinct from frontal activity in

middle latitudes (termed the ‘Arctic Frontal Zone’) has a long history. A maximum in frontal frequencies is found during summer along northern Eurasia from about 60–70° N, best expressed over the eastern half of the continent. A similar relative maximum is found over Alaska, which although best expressed in summer is present year-round. These features are clearly separated from the polar frontal zone in the middle latitudes of the Pacific basin. While some separation between high and middle latitude frontal activity is observed in all

Figure 4 Mean sea level pressure fields (hPa) for (a) January and (b) July based on NCEP/NCAR reanalysis data for the period 1970–99. Note the different contour interval for January (4 hPa) compared to July (2 hPa).

Figure 5 Average seasonal number of extratropical cyclone centers for (a) winter and (b) summer. Results are based on an automated cyclone identification algorithm applied to 6-h sea level pressure fields from the NCEP/NCAR reanalysis for the period 1970–99. Dotted contours are used to highlight areas with more than 3.5 systems per season.

seasons, the summer season is distinguished by the development of a mean baroclinic zone aligned along the Arctic Ocean coastline and associated wind maxima in the upper troposphere. While it has been postulated that the frontal zone arises from contrasts in energy balance between the tundra and boreal forest, it appears that coastal baroclinicity and focusing of the baroclinicity by orography play stronger roles. Regions of maximum summer frontal frequency correspond to preferred areas of summer cyclogenesis over Eurasia and Alaska.

Surface Energy Budget and Cloud Cover

Figure 6 shows typical monthly values of surface radiative flux components for the central Arctic Ocean. The outgoing longwave flux from the surface decreases from about 320 W m^{-2} in summer (when the sea ice surface is melting) to about 200 W m^{-2} in winter. The incoming longwave flux varies between 160 W m^{-2} in winter to 300 W m^{-2} in July. For all months, the net longwave flux is directed away from the surface. The downwelling shortwave (solar) flux is zero during the winter period of polar darkness, rising to about 300 W m^{-2} in June. Because of the high surface albedo (exceeding 0.80 when covered with fresh snow) comparatively little of the solar flux is absorbed by the surface. A fraction of the incoming solar radiation (typically 15%) penetrates into the snow and ice. Net all-wave radiation (net shortwave plus net longwave) is directed away from the surface from October through March and peaks in June at about 80 W m^{-2} . During winter there is a conductive heat flux through the sea ice to the surface. On an annual basis, the sensible and latent heat fluxes together balance 20–50% of the net radiation. During summer, the bulk of the net radiation is used to melt snow and ice. Locally, over areas of open water or

thin ice where strong temperature gradients are formed in the boundary layer in winter, upward sensible heat fluxes may reach 600 W m^{-2} . Condensate plumes emanating from wide ($>10 \text{ km}$) open water areas (leads) that extend to 4 km in the atmosphere have been observed in winter.

The fundamental difference between the surface energy budgets of the Arctic Ocean, glaciers, and tundra in summer is the portion of net radiation used to melt snow and ice. Once the snow is melted from the tundra, energy can be used in sensible heating of the atmosphere and evaporation (turbulent heat fluxes). The consumption of heat through melt on the ocean and glaciers is about four to six times larger than on the tundra. Consequently, sensible heat is transferred from the atmosphere to the surface of the oceans and glaciers, while it is carried from the surface to the atmosphere in the tundra. Evaporation is, on average, the most significant heat sink on tundra and is considerably larger than on the ocean and glaciers.

A key control on Arctic surface energy budgets is cloud cover. Winter cloud fractions range from 40 to 70%, greatest over the Atlantic side where extratropical cyclone activity is most common. Total cloud fractions rise to 70–90% in summer. There is a rapid increase between April and May, characterized by the development of extensive low-level stratus over the ocean. The seasonality of low-level stratus appears to be strongly controlled by the temperature-dependent formation of atmospheric ice. At temperatures below freezing, the saturation vapor pressure over ice is lower than over liquid water, such that ice particles grow at the expense of supercooled droplets. The concentration of ice crystals is smaller than that of cloud condensation nuclei. Hence a given mass of frozen condensate is distributed among smaller numbers of larger nuclei that grow rapidly to precipitable sizes when the

Figure 6 Monthly radiation balance components (W m^{-2}) for the central Arctic Ocean. Notation is as follows: Fl , incoming longwave radiation; Fr , incoming solar radiation; $Fr(1 - \alpha_s)$, solar radiation absorbed at the surface (α_s is surface albedo); $Fl - \epsilon\sigma T^4$, net longwave radiation; $\epsilon\sigma T^4$, outgoing (upward) longwave radiation; and R_n , net radiation. Reproduced from Barry, R.G., Serreze, M.C., Maslanik, J.A., Preller, R.H., 1993. The Arctic sea-ice climate system: Observations and modeling. *Reviews of Geophysics* 31, 397–422.

environment is supersaturated with respect to ice, disfavoring the development of stratus. This can be viewed as a preemptive dissipation of stratus, as the process can prevent the humidity of clear air from reaching saturation. This idea is supported by observations of ice crystal precipitation during the winter months. During summer, when temperatures are higher, the ice crystal scavenging processes are less effective and stratus is more likely to form and persist.

Except for a short period during summer, the net cloud radiative forcing is positive, meaning that clouds have a warming effect at the surface (net radiation at the surface is higher in the presence of clouds). This is basically because the increase in the downwelling longwave radiation flux due to the high emissivity of clouds exceeds the reduction in the downwelling solar radiation flux due to high cloud albedo and to lesser extent cloud absorption. However, cloud radiative forcing is a complex issue, with the sign and magnitude of the forcing depending on the solar flux above the clouds, cloud albedo, optical thickness and temperature, surface albedo, and multiple reflections between the surface and cloud base. Of course during winter, with little or no solar radiation, cloud radiative forcing is always positive.

Air Temperature and Boundary Layer

Winter surface air temperatures decrease sharply from the northern North Atlantic to the central Arctic Ocean (Figure 7(a)). The high temperatures over the Atlantic sector arise from poleward ocean heat transport, which keeps the region free of sea ice, and extensive cloud cover. The lowest winter air temperatures are found over east-central Eurasia in association with the Siberian High. Comparatively higher mean temperatures over the central Arctic Ocean reflect the effect of heat fluxes through areas of open water and thin ice. Low temperatures over the Greenland ice sheet reflect elevation.

Higher summer temperatures over land as compared to the ocean manifest latitude and the transformation of solar radiation into heating the atmosphere from turbulent and upward longwave radiation heat fluxes, as opposed to sea ice melt and seasonal replenishment of the ocean's sensible heat content. These differences in the surface energy budget over land versus ocean (see Surface Energy Budget and Cloud Cover) account for the pronounced temperature gradients along the coast (Figure 7(b)) which are in turn an expression of the summer Arctic frontal zone.

A characteristic feature of the Arctic atmosphere in winter, when there is little or no solar radiation, is a strong surface-based temperature inversion. Away from the Atlantic sector, winter inversions are typically 1000 m deep, with a temperature difference across the inversion layer of 10–12 °C. The winter Arctic inversion can be viewed in terms of an approximate longwave radiative equilibrium. The surface has a longwave emissivity close to one, while the longwave emissivity of the atmosphere is less than one. In longwave equilibrium, the atmosphere must then radiate at a higher physical temperature than the surface, which requires a temperature inversion. However, given that the surface and the atmosphere both radiate to space, maintaining the inversion requires a transport of heat from the south. This provides only a first-order view. Inversion depth and strength vary widely in response to local topographic conditions, winds, cloud cover, and surface fluxes. For example, inversions over the central Arctic Ocean tend to be weaker than over land due to heat fluxes through areas of open water and thin ice. Inversions are also common in summer, although they are weaker than their winter counterparts and are typically separated from the surface by a mixed layer. However, over the Arctic Ocean, shallow surface-based inversions are very common due to sea ice melt, which keeps the surface skin temperature at the melting point, hence leading to the downward sensible heat flux noted earlier.

Hydrologic Budget

Precipitation and Precipitation Minus Evaporation ($P - E$)

Precipitation in the Arctic is difficult to measure accurately because of gauge undercatch of blowing snow, changes in and differences between countries in instrument types and reporting practices, and the sparse precipitation monitoring network. Figure 8 shows the distribution of annual precipitation based on a gridded climatology compiled from several data sources. The highest totals are found off the southeast coast of Greenland (locally >2400 mm) with amounts decreasing

Figure 7 Mean surface air temperature ($^{\circ}\text{C}$) for (a) January and (b) July, based on the University of Washington International Arctic Buoy Programme/ Polar Exchange at the Sea Surface (IABP/POLES) data set. Reproduced from Rigor, I.G., Colony, R.L., Martin, S., 2000. Variations in surface air temperature observations in the Arctic, 1979–1997. *Journal of Climate* 13, 896–914.

northeast to about 400 mm in the Kara Sea. This pattern manifests the pattern of cyclone activity shown in [Figure 5\(a\)](#). High totals are also found over southern Alaska. The lowest annual totals (<200 mm) encompass the Beaufort Sea and the Canadian Arctic Archipelago; these islands are primarily classified as polar desert. The winter pattern is qualitatively similar

to that seen in the annual mean. For example, mean January precipitation ranges from over 200 mm in the northern North Atlantic to less than 10 mm over northern Canada and east-central Eurasia. Summer precipitation is more uniform across the Arctic with markedly higher totals as compared to winter over land areas. This is consistent with seasonal changes in synoptic activity (compare [Figure 5\(a\)](#) and [5\(b\)](#)). Convective precipitation is not uncommon over Arctic land areas during summer.

Winter precipitation is largely stored in the snowpack. Maximum spring snow depths are highly variable due to differences in precipitation, temperature, topographic setting, and redistribution by wind. Values of 20–50 cm over the Arctic Ocean and 40–70 cm over the subarctic can be considered typical. Mean hydrographs for Arctic rivers exhibit a late spring to early summer peak in discharge due to melt of the snowpack.

Direct estimates of evaporation are scanty. However, large-scale estimates of precipitation minus evaporation ($P - E$) (net precipitation) can be obtained through evaluation of the atmospheric vapor flux convergence. Estimated mean annual $P - E$ ([Figure 9](#)) is typically 150–300 mm over land, 200 mm over the central Arctic Ocean and over 1000 mm in the vicinity of the Icelandic Low. Although precipitation over much of the land area peaks in summer, $P - E$ for this season (not shown) tends to be small or even negative. Negative values imply net drying.

Freshwater Budget

The freshwater balance of the Arctic Ocean is a topic of continuing interest. Freshwater storages and transports have typically been calculated with respect to a reference salinity of 34.8 parts per thousand, which approximates the average bulk salinity of the Arctic Ocean. Water lower than this reference

Figure 8 Mean annual precipitation (mm) with estimated adjustments for wind-induced gauge undercatch, changes in instrument types and differences in observing methods. Dotted contours are used to highlight areas with precipitation exceeding 800 mm. Compiled from data provided by Groisman, P., Yang, D., Eischeid, Willmott, C.

Figure 9 Mean annual precipitation minus evaporation ($P - E$) (in mm) based on calculations of the vapor flux convergence using NCEP/NCAR reanalysis data for the period 1970–99. Areas with negative $P - E$ are indicated with dotted contours.

salinity is said to contain freshwater; the lower the salinity, the greater the freshwater content per unit volume.

The total annual freshwater input to the Arctic Ocean is estimated at about 8500 km^3 . The primary inputs are river runoff (38%), the import of fairly low-salinity water through Bering Strait (30%) and positive $P - E$ over the Arctic Ocean itself (24%). The Arctic Ocean is unique in receiving runoff from four of the world's major rivers (the Ob, Yenisei, and Lena in Eurasia and the Mackenzie in North America). These riverine, atmospheric, and oceanic freshwater sources collectively help to maintain a fairly fresh surface layer that extends down to about 200 m, which is often well-mixed down to about 50 m. Relatively warm and salty waters of Atlantic origin are found between 200 and 900 m depth, which if brought to the surface would quickly melt the sea ice cover. However, at low water temperatures of the Arctic Ocean, the density structure is determined by salinity. Hence the fresh surface layer suppresses vertical mixing with the Atlantic layer, and allows sea ice to form readily in winter.

Freshwater export out of the Arctic Ocean and into the North Atlantic is primarily via Fram Strait in the form of low-salinity sea ice (25%) and liquid water (26%), and through the channels of the Canadian Arctic Archipelago, primarily in liquid form (25%). Freshwater export through Fram Strait in particular is believed to impact on the overturning cell of the global ocean through influencing convection in the subarctic gyres which in turn feed the North Atlantic.

Mean annual freshwater input to the Arctic Ocean is roughly an order of magnitude less than the mean freshwater storage in the Arctic Ocean of about $84\,000 \text{ km}^3$. This storage is represented by both sea ice and fairly low salinity near surface waters. Assuming steady state, the relative magnitudes of the mean

storage versus total inputs (or outputs) imply a mean residence time of freshwater in the Arctic Ocean of about a decade.

Variability and Change in Arctic Climate

Arctic climate exhibits pronounced variability on interannual to decadal scales. A major source of variability is associated with the phase of the North Atlantic Oscillation (NAO), which describes mutual strengthening and weakening of the Azores High and the Icelandic Low. Under the positive mode of the NAO (a deep Icelandic Low), positive temperature anomalies are found over the Eurasian Arctic with negative anomalies over northeastern Canada and the northern North Atlantic. In turn, the North Atlantic cyclone track extends deeper into the Arctic Ocean. Broadly opposing anomalies are associated with negative NAO states. The NAO can be viewed as the North Atlantic component of the Arctic Oscillation (AO) (also called the Northern Annular Mode (NAM)). The AO represents the leading empirical orthogonal function of monthly sea level pressure anomalies poleward of 20° N . Pressure variability associated with the AO is characterized by a primary center of action over the Arctic Ocean, strongest in the vicinity of the Icelandic Low, and opposing anomalies in midlatitudes of the Pacific and Atlantic basins. Changes in the AO index hence manifest a transfer of atmospheric mass between the Arctic and middle latitudes. Time series of the AO and NAO are highly correlated. Arctic climate variability is also linked to the El-Niño Southern Oscillation (ENSO), particularly as it relates to variability in the strength and location of the Aleutian Low, the Pacific North American (PNA) teleconnection, and other modes of variability such as the North Pacific Oscillation (NPO).

The period from the 1970s onward has seen pronounced change in the northern high-latitude environment. Increases in surface air temperature encompass all seasons but are strongest in autumn and winter, and are larger than increases observed for the globe as a whole. Paleoclimate evidence suggests that Arctic temperatures of the late twentieth century and onward are the highest of at least the past 2000 years. Analysis of satellite data available since 1979 documents negative linear trends in sea ice extent for all months, with the strongest trend in September, the end of the summer melt season (13% per decade over 1979–2012 relative to 1979–2000 mean; see <http://nsidc.org/>) (Figure 10). A key driver of this seasonal asymmetry in trends is that the spring ice cover is increasing dominated by relatively thin first-year ice, with less of the generally thicker multiyear ice. As it takes less energy to melt out thin ice, the thinner the ice in spring, the lower the ice extent at the end of summer. Thin spring ice also fosters earlier exposure of dark open water areas in summer which strongly absorb solar energy, leading to a warming ocean that fosters more melt. Other changes include increased vegetation growth, with areas of tundra replaced by shrub vegetation, warming and thawing of permafrost, increased discharge of Arctic-draining rivers in Eurasia, and increased coastal erosion due to a combination of sea ice retreat that allows for stronger wave action, and a warming ocean.

Climate models project that the effects of rising concentrations of atmospheric greenhouse gases will be especially

Figure 10 September sea ice extent, 1979–2012, with linear least squares fit (blue line), based on analysis of satellite passive microwave data distributed by the National Snow and Ice Data Center, Boulder, Colorado.

strong in the Arctic due to feedbacks in which variations in sea ice and snow extent, the stability of the lower troposphere, and thawing of permafrost play key roles. However, regional patterns of Arctic warming differ greatly among simulations. Projected warming is generally strongest for autumn and winter, largely because of the delayed growth of sea ice, which allows for large fluxes of heat from the ocean to the atmosphere. Retreat of snow cover and sea ice is accompanied by increased winter precipitation. Observed changes in the Arctic environment over the past decade are generally viewed as reflecting the combined influences of natural variability in patterns of atmospheric and oceanic circulation having strong regional expressions, superposed upon a general warming linked to fossil fuel burning.

Synopsis

Arctic haze is composed of aerosols – particles and gases – that have increased concentrations in the lower atmosphere across the Arctic regions in late winter and spring. Arctic haze is derived from industrial and wildfire emissions released in continental regions surrounding the Arctic and then is transported to the Arctic over spatial scales of several thousands of kilometers. The haze particles contain sulfate, sea salts, crustal materials, organic components, black carbon, and trace amounts of heavy metals, some of which are characteristic of industry-specific pollution sources.

Introduction

Arctic haze is composed of aerosols – particles and gases – that have increased concentrations in the lower atmosphere across the Arctic regions in late winter and spring. Arctic haze is derived from industrial and wildfire emissions released in continental regions surrounding the Arctic and then is transported into the Arctic over spatial scales of several thousands of kilometers. The gases and particles that constitute arctic haze reside mainly near the meteorological boundaries of the arctic front, a system surrounding the North Pole, reaching its southernmost extent in late winter (February–March). The Arctic is highly sensitive to warming from greenhouse gases and is integral to the global temperature gradient that drives the main circulation of the atmosphere. As opposed to greenhouse gases, the arctic haze includes components that warm and cool the atmosphere. But the haze processes are very complex and the relative importance of the arctic haze remains unclear.

During late winter the system of arctic haze is roughly as large in areal extent (the region encircled in [Figure 1](#)) as the African continent. After the spring polar sunrise, the ‘haze’ can be visible to the eye, especially when viewed edgewise from an aircraft. The haze reduces direct solar radiation at the surface, whitens the sky, and causes slight warming of the Earth–atmosphere system.

The haze was first noted by Murray Mitchell Jr, in 1956, when flying on ‘Ptarmigan’ weather reconnaissance missions in the Arctic. Mitchell recognized that the constituents were probably of the same order as the wavelength of visible light. He speculated that the origin of the unknown haze particles might be quite distant since small submicrometer particles have long lifetimes in the atmosphere. Investigations of chemical composition and optical properties of arctic haze were conducted in the early 1970s and led to the recognition of an arctic-wide pollution phenomenon. The general picture of arctic haze being pervasive, extensive, and caused by circum-polar industrial emission unfolded during research carried out in the 1980s and has continued through the 2010s with more specific characterization of chemical components in particles and more detailed attribution of contributing sources and meteorology.

If one considers the geographic location of pollution sources and the nature of atmospheric circulation at high

latitudes (see the next section), it is apparent ([Figure 1](#)) that the more numerous and more northern Eurasian pollution sources are likely to contribute larger amounts of pollution to the Arctic than the sources in North America. The lack of sunlight, coupled with the snow-covered surface that reflects the little sunlight received back to space, results in especially strong cooling of the surface layers and buildup of surface-based temperature inversions. Mixing is greatly inhibited under such circumstances. In much of the Arctic, most especially around the Siberian High, cloudiness is thin and sparse. These factors increase the residence time of pollutants in the Arctic, resulting in prolonged high concentrations of particles in the arctic atmosphere.

Seasonal and Geographic Variations of the Arctic Haze and Meteorological Transport

In winter, the arctic air mass extends throughout the high Arctic and down over Eurasia and North America. Arctic haze has been described as having a ‘dome,’ 7–8 km deep over the pole with shallow tongues of air, 0–5 km deep spilling southward over the land masses. This air mass is statically stable because of the strong temperature inversions and has relatively small cloud water or ice content. There is a close connection between outbreaks of arctic haze and transport along or within anticyclonic pathways in the atmosphere. In the polar regions since the arctic air is stable, particles may remain airborne for weeks. The connection between arctic haze and anticyclonic conditions suggests that a reason why haze lasts so long is partly due to the lower frequency of rain and snow cleansing mechanisms.

Transport of pollution episodes into the Arctic is often controlled by the midnorthern Eurasian high, extending over Kamchatka and another cell over the Alaska area, or steered by cyclonic systems in the Barents Sea. Studies of the meteorological patterns indicate that the transport of arctic haze is associated with a quasi-stationary ‘blocking’ pattern in the atmosphere. This provides conditions for poleward transport of midlatitudinal air pollution, particularly from the European and northern Asian sectors (Eurasia). The seasonal variation of this blocking, along with scavenging and other removal processes, is important for understanding the annual cycle of the arctic air pollution.

Figure 1 Locations of large sources of sulfur dioxide emissions (in units of millions of metric tons) in the high-latitude Northern Hemisphere that influence the Arctic. Map courtesy of Leonard Barrie.

Arctic pollution in midwinter has substantial contributions from sulfur dioxide. This gas is oxidized to form sulfate (SO_4^{2-}) in particles by both photochemical processes in spring and particle processes in winter. Combining the increased residence time with springtime sunlight makes the polar atmosphere work like a large chemical reactor, producing increasing mass of particles that scatter light to form the persistent haze.

Low-level liquid cloud cover becomes increasingly important throughout the Arctic as the summer progresses and areas of open water increase. Cloud decks form when warm moist air flows over cold icepack; drizzle often accompanies the cloud. The summer arctic stratus is one of the most pervasive and persistent cloud systems on the planet. The turnover and almost constant drizzle is instrumental in cleansing the arctic atmosphere, reducing concentrations of arctic haze to insignificant levels. As a result, the concentration of arctic haze undergoes a strong seasonal variation with maximum in spring and minimum in summer. **Figure 2** shows the strong seasonal variation of sulfate aerosol concentration sampled in the Canadian Arctic over nearly 30 years. **Figure 3** shows similar seasonal cycles and long-term trends for Barrow, Alaska. Notable is the reduction in the contribution of sulfate. This 'arctic air mass' picture provides a rough understanding of the more persistent and larger features of arctic air pollution.

The map of annual emissions of sulfur dioxide with superimposed arctic air mass (**Figure 1**) helps identify the major sources and currents of pollution-derived material affecting the Arctic. Thus, on the basis of the relatively strong source region in the central and western Eurasia sector, the occurrence of a deep lobe of the arctic air mass over much of this source, the occurrence of a poleward flowing circulation over this source area, and the absence of precipitation, clouds, and turbulence along the pathway, it is clear that Eurasia is of greater importance than North America as a source region for the arctic haze.

Chemical Composition of the Arctic Haze

The chemical composition of aerosol has been measured at various arctic monitoring sites since the 1970s in order to identify the origin of the hazy layers. Although sulfate contributes a major fraction of particle mass, the haze also contains sea salts, crustal materials, organic components, black carbon, and trace amounts of heavy metals, some of which are characteristic of industry-specific pollution sources (**Figure 4**). Chemical measurements through 2008 have continued to show the strong seasonal variation (discussed in the last section), with maximum occurrence of the arctic haze in the

Figure 2 Trends and seasonal variations of (a) sulfate and (b) black carbon (BC) aerosols observed at the Dr Neil Trivett Global Atmospheric Watch Observatory, Alert, Nunavut, Canada, in ng m^{-3} . Sulfate is from the ion chromatography analysis of weekly integrated high-volume filter samples, and the BC is from weekly averaged light absorption measurements (aethalometer) adjusted to elemental carbon concentrations derived from a thermal method. The 1976–1977 data are from Rahn and McCaffrey (1980). Vertical bars for the 1997–2008 data are the standard deviation of the monthly average. Reprinted from Quinn, P. K., Bates, T. S., Schulz, K., Shaw, G. E., 2009. Decadal trends in aerosol chemical composition at Barrow, Alaska: 1976–2008. *Atmospheric Chemistry and Physics* 9 (22), 8883–8888. doi:10.5194/acp-9-8883-2009.

late winter and early spring, consistent with meteorological drivers for this pattern.

A large fraction of the arctic haze is sulfate. Note from Figure 1 that the Eurasian sulfur dioxide emissions in areas liable to influence the Arctic are about a factor of 2–4 times larger than for

North America. Note also that the major Eurasian sulfur dioxide emission sources are $5\text{--}10^\circ$ higher in latitude in comparison to those in North America. This, along with the fact that the arctic air mass extends down further over Eurasia, suggests that the major contribution to arctic haze is from the Eurasian sources.

Figure 4 Time series of measured atmospheric aerosol component concentrations at Barrow, Alaska. (a) organic functional groups; (b) source-related factors; (c) sea salt, other trace elements, sulfur (represents approximately one-third of the sulfate mass), and crustal components; and (d) sea salt. Bar widths correspond to durations of collected filters. Inset pies indicate time-weighted seasonal averages. Reprinted from Shaw, P. M., Russell, L. M., Jefferson, A., Quinn, P. K., 2010. Arctic organic aerosol measurements show particles from mixed combustion in spring haze and from frost flowers in winter. *Geophysical Research Letters* 37, doi:10.1029/2010gl042831.

The emission sources of the arctic haze were determined to be of Eurasian origin using a chemical fingerprint based on the ratio of vanadium to manganese concentrations in the collected filtered samples of the arctic haze. This simple tracer system immediately suggested that the greatest fraction of arctic haze aerosol was derived from Eurasian industrial sources, especially in the eastern sectors. The reason is that the former Soviet Union and eastern European nations have been using coal-burning as major power sources, while the western hemisphere nations are heavy users of petroleum products, laced with vanadium used as a catalyst in the cracking process. The arctic haze value of V/Mn was very low, consistent with a coal-burning source. Concentrations of black carbon were also elevated, consistent with the dirtier combustion that takes place in inefficient coal power plants of the type used in the former Soviet Union. This basic picture of the sources and transport mechanisms for the arctic haze was recognized quite clearly during the 1970s.

Aircraft-based measurement programs, including the Arctic Gas and Aerosol Sampling Programs, the German-Russian aircraft 'Arctic Haze/Merise' campaigns of 1993–95, the Arctic Study of Tropospheric Aerosol campaign, the European Arctic Aerosol Study, and Arctic Research of the Composition of the Troposphere from Aircraft and Satellites campaigns, have directly sampled the arctic haze, and the changes in the composition of the arctic haze have been tracked for more than 40 years. Sulfur in the form of sulfate continues to be a substantial fraction of particle mass identified in the arctic haze, even at the higher altitudes, but recent measurements at Barrow confirm an average decrease of non-sea-salt sulfate emissions of a factor of four over 30 years (Figure 5). By comparison, the observations from Alert (Figure 2) have shown a decrease in sulfate of about a factor of two over approximately the same period.

By combining the meteorological trajectory models with geographic information and inventories of chemical emissions,

recent investigations have identified a number of specific geographic locations in Eurasia that have high potential as major emission sources. For example, a Ni–Cu smelting complex at Norilsk is probably one of the major contributors to the haze. But in addition to sulfur-containing particles and heavy metals, carbonaceous particles will also reach the Arctic. During polar winter, the contributions of organic compounds consist largely of primary marine-derived components (Figure 4). After polar sunrise the organic fraction can increase photochemically so that during spring and summer organic carbon is a major aerosol constituent, accounting for as much if not more submicron particle mass than the sulfate.

Figure 5 Concentrations of (a) non-sea-salt (nss) sulfate and (b) non-crustal (nc) Vanadium averaged over the haze season (January–April) and (c) the nss sulfate (SO_4^{2-}) to ncV ratio. The 1976–1977 data are from Rahn and McCaffrey (1980). Reprinted from Quinn, P. K., Bates, T. S., Schulz, K., Shaw, G. E., 2009. Decadal trends in aerosol chemical composition at Barrow, Alaska: 1976–2008. *Atmospheric Chemistry and Physics* 9 (22), 8883–8888. doi:10.5194/acp-9-8883-2009.

Recent studies indicate that combustion emissions account for more than 60% of the organic mass (OM) that make up arctic haze particles, but the Eastern and Western regions of the Arctic are largely influenced by two different urban and industrial centers with different fuel usage resulting in particles with different chemical compositions. The high-sulfur coal and wood burning in northeastern Europe (Poland and the Russian Kola Peninsula) contribute to the haze in the eastern (European) Arctic, and the oil-burning and forest fires in northeastern Asia (Siberia) influence the haze in the western (North American) Arctic (Figure 6). The organic components of haze include several types of organic molecules. Organic acid and alcohol group contributions measured by infrared spectroscopic techniques account for almost 25% of the combustion organic functional groups, reflecting the composition expected for photochemical oxidation of incompletely combusted fuels. Aerosol mass spectrometric measurements confirm the highly oxidized organic composition of arctic haze particles, similar to that observed for combustion emissions in the subpolar source regions. One interesting chemical consequence of the regional differences is that the higher coemissions of sulfate from coal-burning in northeastern Europe produce significant concentrations of another type of organic component – organosulfate functional groups – which account for as much as 10% of organic particles over the Barents and Greenland Seas. Long-lived organic compounds such as polychlorinated aromatics and pesticides have also been measured in both arctic air pollution and snowpack.

Optical Transparency and Climatic Effects

In the early 1970s, unexpectedly high values for atmospheric turbidity were reported at the McCall Glacier in the Brooks Range in Alaska. In trying to understand the physical cause of the high turbidity, additional measurements were made of the wavelength dependence of optical extinction caused by the haze and the angular distribution of sky brightness. These measurements confirmed Mitchell's earlier suspicions that the winter arctic haze consisted mainly of small aerosols. During the early 1970s, arctic haze over Alaska was found to be layered by flying a sun photometer aboard a light (Cessna) aircraft. The AGASP experiments of the 1980s demonstrated that the layers consist of aerosol particles that can have climatic effects by interacting with the solar radiation field all across the Arctic. In addition to the submicrometer haze, there is often another source of haziness in the Arctic from precipitations of small ice crystals, which sometimes form in clear air. Such 'diamond dust,' so-called because of its sparkling appearance, can also reduce visibility and interact with the radiation field.

Scattering and absorption of sunlight by the arctic haze was shown to have a slight warming effect on the Earth-atmosphere column, of magnitude about 0.1 °C per day, because the light absorbing properties of black carbon particles lower the albedo. Since the surface albedo of sea ice is so high, this absorption tends to be more important than the slight cooling at the surface caused by the scattering of light. In the winter months, there may be a slight warming of the arctic

Figure 6 Potential source contribution functions of (a) sulfate, (b) organosulfate functional group concentrations, (c) the total OM1 measured, and (d) the combustion-derived OM measured during a cruise in the North Atlantic and Arctic Oceans in 2008, as well as (e) the combustion-derived OM measured at Barrow in 2009. The higher potential source regions are indicated by red and the lower potential source regions are indicated with blue. Reprinted from Figures 5 and 6 of Frossard, A. A., Shaw, P. M., Russell, L. M., Kroll, J. H., Canagaratna, M. R., et al., 2011. Springtime Arctic haze contributions of submicron organic particles from European and Asian combustion sources. *Journal of Geophysical Research – Atmosphere* 116, doi:10.1029/2010jd015178.

atmosphere caused by the interaction of the aerosol with outgoing infrared radiation.

However, in addition to the slight climate effects caused by absorption and scattering of light by the arctic haze aerosols, there may be subtle and so far not well-evaluated influences on climate from indirect radiative effects. These may result from the modification of cloud properties, since the arctic haze introduces new sources of cloud condensation nuclei and, possibly causes dehydration.

Ecological Implications

Compounds such as pesticides, polychlorinated biphenyls, persistent organics, as well as trace metals are detected throughout the arctic basin in the atmosphere and also in the surface land and sea domains and scattered throughout the region's biome. Most of the atmospheric pollution and some of the surface and biological pollution is undoubtedly caused from the arctic haze phenomena. But it should also be recognized that in places in the Arctic the surface concentrations of pollutants can be extremely small, even during times when the air is quite contaminated. This of course is due to the long residence time of the haze.

In addition to simple transport of material through the atmosphere, another depositional mechanism was suggested that involves a fractional distillation. The surprisingly high concentration of organic material is determined in part by the temperature-dependent partitioning of the low volatility compounds. Substances with low vapor pressure preferentially accumulate in the polar regions.

Aerosols and gases are scrubbed out of the atmosphere in precipitating air masses. Many of these are over oceanic regions in the North Atlantic, the Norwegian Sea, and

possibly in the Bering Sea. These are important world fisheries and the consequences of dumping industrial pollutants that had congregated in the arctic atmosphere are unknown.

Introduction

The world ocean is a key element of the physical climate system. The ocean contains 97% of the world's water and covers an area of 71% of the globe. As a reservoir, the ocean supplies water vapor to the atmosphere that brings rain and snow over land surfaces. About one-third of the precipitation over land originates from water evaporated from the ocean. The water vapor in the atmosphere is the most important gaseous absorber for solar and terrestrial radiation and accounts for about half of the atmosphere's natural greenhouse effect. The process of evaporation accounts for approximately half of the surface cooling balancing the heating by absorption of solar radiation.

Because of the asymmetric insolation of the Earth's surface by solar radiation, the oceans act as a large energy and heat transport system from the Equator to the poles. The deep-ocean circulation that is critical for this transport is mostly driven by variations in the density of sea water. Ocean salinity is an important contributor to these variations and varies with latitude in the upper layers of the oceans. The surface salinity depends on the fresh water flux at the ocean surface and is relatively high in the subtropics where evaporation exceeds precipitation, whereas it is relatively low in the tropics and middle and high latitudes where precipitation dominates.

The most comprehensive publication about the world water balance was written by Baumgartner and Reichel in 1975. They assembled different estimates of the water balance over continents, river basins, and oceans to calculate a global water balance. This pioneering work resulted in global maps of evaporation and precipitation that even today are widely used by meteorologists, oceanographers, climatologists, and hydrologists. The definition of the water balance and its

components used here follows the work of Baumgartner and Reichel.

Assuming that the amount of water on Earth is not changing with time, the long-term average of the water balance for a unit area of the Earth's surface can be written as eqn [1].

$$P = E + D \quad [1]$$

In eqn [1], P is precipitation, E is evaporation, and D is discharge or river runoff. This balance states that water added to the surface by precipitation is partitioned between E and D . Although globally precipitation and evaporation are balanced, the large differences in the components P , E , and D over land and over ocean produce the world's water cycle, shown schematically in Figure 1. The units used throughout the article for E , P , and $E-P$ are mm d^{-1} . In general, total evaporation exceeds precipitation over oceans, which is compensated for by the runoff of rivers from the continents, where precipitation exceeds evaporation.

In the following sections the focus will be on the different methods used to determine the freshwater flux at the oceans surface: E , P , $E-P$ will be considered in detail. The heat transport within the oceans is beyond the scope of this article (see **Air–Sea Interaction: Momentum, Heat, and Vapor Fluxes**). The second section gives an overview of different techniques that can be used to determine the fresh water flux, followed by a description of the fresh water flux climatology as derived from satellite data. This is followed by a short consideration of the role of river runoff, and finally some conclusions are presented.

Methods for Determining E , P , and $E-P$

Basically, there exist three different methods for determining the components E and P as well as $E-P$. Traditional

Figure 1 Schematic representation of the world water cycle E and P denote evaporation and precipitation over oceans and land (denoted by subscript O and L , respectively). D is the discharge or river runoff of water from the continents to the oceans and MT is the moisture transport in the atmosphere.

estimates of E are based on *in situ* measurements of surface wind speed U , specific humidity of air Q_a , and sea surface temperature T_s . These are used within the so-called bulk aerodynamic formula to parametrize the evaporation. P is estimated by analyzing actual weather reports using an empirical parametrization. The resulting estimates are interpolated and extrapolated to construct global maps of E and P .

Recently, satellite data have been used to derive the same basic state variables near and at the ocean surface using empirical and physical retrieval schemes. Again these quantities are used to parametrize E using the bulk aerodynamic formula. Many algorithms for estimating rainfall using almost the whole electromagnetic spectrum have been developed during the last 20 years (see **Satellites and Satellite Remote Sensing: Precipitation**). These satellite algorithms are used alone and in conjunction with *in situ* data and model results to give best estimates.

The third method is the so-called moisture budget method, which make use of global-scale analyzed water vapor fields or measurements of atmospheric water vapor by rawinsondes in the form of four-dimensional data assimilation (see **Statistical Methods: Data Analysis: Time Series Analysis**). The global distribution of $E-P$ is then computed from the residuals of water vapor transport in the atmosphere using large-scale numerical models.

Traditional Estimates from *in situ* Measurements

Most of our present knowledge of fresh water fluxes is derived from weather observations on special weather ships, buoy data, and also data from merchant ships participating in the Voluntary Observing Ship system. Many of these data have been organized into the Comprehensive Ocean Atmosphere Data Set which has been used to derive climatologies of the energy fluxes and the fresh water flux at the sea surface. The major disadvantage of ship-based estimates of E and P is that the

observation base is not very good for either parameter. The coverage is mostly obtained along shipping lanes, which may be sufficient in the North Atlantic, North Pacific, and the Mediterranean but is not sufficient in the Tropics and all southern oceans. Additionally, the concentration along shipping lanes can introduce a fair weather bias, since ships try to avoid bad weather.

Whereas the measurement quality for the basic state variables used for the parametrization of E is relatively good on ocean weather ships and research quality buoys, it is less good on the voluntary observing ships. Although much effort has been put into correcting errors on the basis of individual ship measurements during the last few years, the global heat balance has not been closed, mostly because of the low observation density and deficiencies in the bulk aerodynamic formula. The determination of precipitation is even more difficult. It is largely based on the observed actual weather and parametrizations that convert the weather code into rainfall amount. The conversion schemes were developed from data that are not representative of the global oceans, so it became necessary to correct under-estimated precipitation in the Tropics by empirical temperature-dependent corrections. Incorporation of P measurements from islands in data-sparse regions is also very difficult, because of the influence of island terrain on the rainfall. Comparisons of these precipitation fields with satellite-derived fields exhibit large differences even at the climatological scale.

Remote Sensing of $E-P$

Remote sensing of evaporation is based mostly upon the derivation of basic state variables, wind speed, sea surface temperature, and near-surface atmospheric specific humidity, and the parametrization of the evaporation using the bulk aerodynamic formula. Wind speed can be obtained from either passive or active microwave systems. The active system relates the backscattered energy to the wind speed at a reference level

over sea surface (e.g., 10 m) and is also able to deliver wind direction information. The passive systems rely on the surface emission change due to wind-induced sea surface roughness and partial foam coverage. The root-mean-square (rms) errors on an instantaneous time scale for both systems are on the order ± 1.3 to $\pm 2 \text{ m s}^{-1}$. Remote sensing methods for the near-surface specific humidity make use of a vertically integrated water vapor content (obtained from a passive microwave instrument such as the Special Sensor Microwave/Imager (SSM/I)) as a predictor. Several techniques ranging from linear regression analysis to neural networks have been used to deduce the near-surface humidity with rms errors of $\sim \pm 0.7 \text{ g kg}^{-1}$ on the monthly time scale. Estimates of sea surface temperature are deduced from passive infrared sensors like the Advanced Very High Resolution Radiometer (AVHRR). The largest problem with this method is the cloud clearance of the satellite scene, because otherwise the determined T_s would be negatively biased. Accounting for the surface skin effect, rms errors for the best satellite methods are $\sim \pm 0.2 \text{ K}$. Estimates of sea surface temperature with not much less accuracy are also possible employing passive microwave measurements at frequencies between ~ 50 – 10 GHz that are available from TRMM's TMI and will shortly be available from the new Advance Multifrequency Scanning Radiometer onboard the Aqua and ADEOS-II satellites. The big advantage of those estimates is the much better coverage because clouds are almost transparent at those frequencies allowing an undisturbed view of the ocean surface. However, infrared estimates of sea surface temperature remain of high importance for the computation of evaporation climatology since estimates of sea surface temperature from SSM/I measurements were not possible with sufficient accuracy. Recently, some new methods have been developed that circumvent the bulk formula in the retrieval process by relating the satellite data directly to an existing flux data set, e.g., re-analyses of fields derived from *in situ* data that are assumed to be true. The accuracy of all methods is comparable at a level of $\pm 30 \text{ W m}^{-2}$ and $\pm 15 \text{ W m}^{-2}$ at weekly and monthly time scales, respectively.

As mentioned in the previous section, there are not sufficient conventional and surface-based radar rainfall estimates over the oceans for the derivation of rainfall fields. A reasonable alternative is the use of satellite remote sensing. Remote sensing of rainfall from satellites started with the statistical analysis of the reflectivity and emissivity of the upper cloud layers at visible and infrared wavelengths, respectively. Because of the small physical correlation between the signal and the rainfall at the surface, this technique leads to acceptable results only if the derived rainfall is integrated over space and time. Owing to the strong variability of rainfall, rainfall climatologies derived using this technique with data from geostationary satellites with their high repetitive cycle build are still the backbone of today's rainfall analyses.

Over water surfaces, passive microwave radiometers deliver a much better information base. The signal at frequencies below 30 GHz is mostly determined by the emission from rain water, which leads to a strong increase of the brightness temperature over the cold background of the sea surface. For higher frequencies, the brightness temperature decreases owing to scattering by ice particles. This information can also be used to estimate the rainfall rate at the surface.

Since the launch of the first SSM/I onboard the satellites of the Defense Meteorological Satellite Program (DMSP) in 1987, a continuous time-series of data exists from at least one satellite. Many algorithms have been developed to analyze rainfall using these measurements. On the basis of numerous algorithm intercomparison projects, it has proved almost impossible to find a so-called standard algorithm that performs best for most of the situations investigated. The variability of the cases analyzed showed the quality of some algorithms under certain conditions, but not of one prevailing algorithm. In many cases it was found that the accuracy of the validation data was not sufficient to classify the quality of the satellite algorithms. A prominent data set using combinations of geostationary satellite data, passive microwave data, and rain gauge data is that produced by the Global Precipitation Climatology Project (GPCP).

With the launch of the satellite of the Tropical Rainfall Measuring Mission (TRMM) in 1997, for the first time a space-borne radar can be used to derive the three-dimensional structure of rainfall and the surface rainfall. The combination of instruments onboard the TRMM satellite can be considered as a reference for methods applied to other instruments in space. A calibration of rainfall estimates from other satellites like the SSM/I then delivers an optimal combination of accuracy and temporal/spatial sampling and subsequently consistent rainfall distributions.

Moisture Budget Methodology

The moisture budget methodology tries to compute $E-P$ as a residual from the large-scale atmospheric transports of water vapor using global analyses and re-analysis data sets produced with four-dimensional data assimilation schemes. This technique has a long history, although it usually makes use of rawinsonde data directly. $E-P$ is computed from eqn [2], which is the vertically integrated (from the top of the atmosphere to the surface) equation for the conservation of water vapor.

$$E - P = \frac{\partial W}{\partial t} + \nabla \cdot \frac{1}{g} \int_0^{p_s} q \mathbf{v} dp \quad [2]$$

W is the total precipitable water, q is the specific humidity, p is pressure (with p_s being the surface pressure), $\mathbf{v}$ is the velocity vector, and g is the standard gravity. Many comparison studies between precipitation fields produced routinely and the GPCP data set found discontinuities in the analyses due to changes in the data assimilation system. Another problem was that rainfall maxima in the analyses were often in the wrong place and too strong. In general, the assimilation systems have been much improved during the last ten years and are more or less consistent with satellite-derived data sets. However, use of this method with different analysis and re-analysis products from the European Center for Medium-range Weather Forecasts (ECMWF), the National Centers for Environmental Prediction (NCEP), and the National Aeronautics and Space Administration (NASA) as input and comparisons to pure model-computed $E-P$ exhibited large differences. The most critical part of this method is the dependence of the moisture budget on the divergence of the velocity field. This is of special importance

in the Tropics, where the divergence field is not very well known.

River Inflow

The inflow of fresh water from rivers is not included in most ocean surface fresh water data sets derived from satellites and is also neglected in the residual approach, but it is significant to the global fresh water balance of the ocean. Baumgartner and Reichel estimated from a global hydrological balance calculation that the contribution of river runoff to the balance is as high as 10% of the contribution of precipitation. It might be thought that the impact of the fresh water inflow from the rivers on the buoyancy would be local in comparison to the size of the ocean basins. However, the impact of major rivers like the Amazon or Congo is observable several hundred kilometers away from the mouths of the rivers. Neglecting this contribution would increase the average salinity of the upper Atlantic ocean (the first 50 m) by 1.5 psu after 10 years of integration of a numerical ocean model.

Two major runoff data sets are the Global River Discharge Catalogue published by the International Hydrography Program (IHP) and that issued by the Global Runoff Data Center, and these form the backbone of information on river runoff. IHP data consists of a selection of monthly discharges at 949 stations over six continents (Africa, Asia, North America,

South America, Europe and Australia/Oceania), but only 219 stations are listed as corresponding to a direct discharge into an ocean basin. The length of the individual data sets is 19.3 years on average, but varies from 1 year to 100 years. Additionally, a great disparity exists between the different continents, with Europe and North America presenting the longest records. Not included in either data set is the runoff from Arctic and Antarctic regions and the inflow of fresh water from ground water sources.

Analysis of the monthly mean climatology of the direct contribution of rivers to the fresh water flow into the ocean, considering only rivers for which time records longer than two years exist, sums to ~ 0.57 Sv ($1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$). This estimate is much lower than that of Baumgartner and Reichel, who found 0.73 Sv, which also includes contributions from regions beyond the polar circles, which they estimated from other sources.

Climatology of $E-P$ Derived from Satellite Data

Figure 2, Figure 3 and Figure 4 show the seasonally averaged global maps of evaporation, precipitation, and $E-P$ derived from AVHRR and SSM/I data, on a grid with $1^\circ \times 1^\circ$ resolution. The data set was constructed by averaging instantaneous estimates of the components and the flux over 11 years (1987–98).

Figure 2 Climatological seasonal averages of evaporation in mm d^{-1} as derived from satellite data: (a) December, January, February; (b) March, April, May; (c) June, July, August; (d) September, October, November.

Figure 3 Climatological seasonal averages of rainfall in mm d^{-1} as derived from satellite data: (a) December, January, February; (b) March, April, May; (c) June, July, August; (d) September, October, November.

Maximum values of evaporation up to 9 mm d^{-1} are observed over the Kuroshio and Gulf Stream regions in winter (Figure 2(a)) and minimum values below 1 mm d^{-1} are seen in the eastern equatorial Pacific and Atlantic during all months. Large areas with high evaporation rates of $5\text{--}6 \text{ mm d}^{-1}$ are found in the main Trade Wind belts between about 10° and 40° latitude in both the Northern and Southern hemispheres. These high evaporation regions are the major sources of atmospheric water for the global hydrological cycle. Whereas during Northern Hemisphere winter and spring the maximum extent and the highest values are found north of the Equator (Figure 2(a) and 2(b)), maximum evaporation is observed in the southern Indian, Atlantic, and Pacific Oceans during Northern Hemisphere summer and fall (Figure 2(c) and 2(d)).

The global precipitation pattern is dominated by a strong band of precipitation circling the globe just north of the Equator. This is the region where the northern and southern Hadley circulation cells meet, forming a region of strong surface convergence known as the Intertropical Convergence Zone (ITCZ). Where the maximum precipitation on an annual scale exceeds 6 mm d^{-1} . Another convergence zone in the western tropical Pacific, known as the South Pacific Convergence Zone (SPCZ), is somewhat broader, with precipitation values similar to those in the ITCZ. It extends from the region of Indonesia and the Philippines south-east across the southern Pacific. With the onset of the summer monsoon, the ITCZ, which was earlier

located in the southern Indian Ocean, shifts to its northernmost location and merges with the Monsoon trough giving rise to copious rainfall over the Indian subcontinent and the adjacent seas, namely the Arabian Sea and Bay of Bengal (Figure 3(c)).

On an annual scale, the region off the Indonesian islands receives a maximum rainfall of more than 10 mm d^{-1} . Outside the two convergence zones, precipitation rates are significantly lower, with the exception of two regions. Precipitation rates are quite high over the Gulf and Kuroshio Streams, with values as high as in the ITCZ during the period November to March (Figure 3(a)). This feature has not been recognized in rainfall climatologies derived from routine weather observations.

At tropical and subtropical latitudes, between about 15° N and 40° N and between 5° S and 30° S , the eastern parts of the Pacific and the Atlantic ocean are regions where precipitation is below 1 mm d^{-1} . A similar region is found in the Indian Ocean along the east coast of Africa and Saudi Arabia during all months, with a maximum extent over the whole Arabian Sea during winter (Figure 3(a)). In the Southern Hemisphere, west of Australian coast, another minimum is observed, which has its maximum extension during the Southern Hemisphere spring (Figure 3(d)).

The patterns of precipitation and evaporation exhibit quite different spatial distributions. Precipitation maxima occur in the global convergence regions, while evaporation maxima

Figure 4 Climatological seasonal averages of $E-P$ in mm d^{-1} as derived from satellite data: (a) December, January, February; (b) March, April, May; (c) June, July, August; (d) September, October, November.

occur in regions of high surface humidity gradient and wind speed. On a monthly time scale, values of E exhibit much less spatial structure than fields of P . From this it is clear that the $E-P$ monthly temporal variability is dominated by variations in location and intensity of rainfall and the spatial structure in $E-P$ is also dominated by the P field.

However, on the climatological time scale, fields of $E-P$ consist of signatures of both evaporation and precipitation fields. The ITCZ and SPCZ appear prominently as regions of fresh water supply to the ocean. In these regions the fresh water flux from atmosphere to ocean is generally larger than 4 mm d^{-1} . With the exception of the SPCZ, precipitation decreases rapidly with latitude to the north and to the south of the ITCZ, while evaporation remains strong or even increases, causing positive values of the fresh water flux.

The strongest gradients in the fresh water flux fields occur in the boundary regions between the negative values of 4 mm d^{-1} within the ITCZ and the strong positive flux regions to the north and south, with values up to 6 mm d^{-1} . Poleward from the evaporation regions, the fresh water flux is relatively small. The evaporation fields generally decrease toward the poles primarily as a result of the decrease in the humidity difference, except during wintry arctic cold air outbreaks which often lead to very high evaporation rates and therefore to positive fresh water fluxes. Although evaporation is quite high, large negative values of $E-P$ can

be found in the Gulf Stream and Kuroshio regions, below -4 mm d^{-1} during the winter owing to high precipitation, while in all other months evaporation almost balances precipitation.

An analysis of the fresh water flux on a seasonal scale (Figure 4(a)–(d)) reveals that the eastern parts of the Arabian Sea, the Bay of Bengal, and the South China Sea all have negative values of fresh water flux during summer (Figure 4(c)) and autumn (Figure 4(d)). Further, on an annual scale, it can be seen that the eastern equatorial Indian Ocean, the Bay of Bengal, and the Kuroshio and the Gulf Stream regions all exhibit negative fluxes. The regions of positive flux are over the north-west Arabian Sea and the southern Indian Ocean south of 20° S . Also, the North Atlantic and the South Atlantic exhibit positive fluxes on both sides of the ITCZ.

Discussion and Conclusion

Table 1 shows how existing estimates of the fresh water flux and its components differ from some examples of estimates from different sources found in the literature. Whereas the older estimates from observations are comparable to the results from General Circulation Models, the satellite estimates differ considerably from all of them. However, today

there is no agreed true value for $E-P$. Current results of global analyses seem not to be very reliable, but centers like ECMWF are improving the assimilation of rainfall estimates from satellite data, and these will be operational in a few years. Satellite data sets have great potential to be improved in the future by using sophisticated methods of intercalibration between different satellites. In the case of basic state variables U , Q_a , and T_s , improvements are expected from intercomparison of the satellite estimates with high-quality surface-based measurements.

Introduction

The maintenance of the Earth's climate depends on a balance between the absorption of heat from the Sun and the loss of heat through radiative cooling to space. For each 100 W of the Sun's radiative energy entering the atmosphere nearly 40 W is absorbed by the ocean – about twice that absorbed in the atmosphere and three times that absorbed by land surfaces. Much of this heat is transferred to the atmosphere by the local sea to air heat flux, a major component of which is caused by the evaporation of water vapor. Although about 90% of the evaporated water falls back into the sea (*see Air Sea Interactions: Freshwater Flux*), the remainder represents about one-third of the precipitation which falls over land. The geographical variation of the atmospheric heating drives the weather systems and their associated winds. The wind transfers momentum to the sea, causing waves and the wind-driven currents. Major ocean currents transport heat poleward and at higher latitudes the sea to air heat transfer significantly ameliorates the climate. Thus the heat, water vapor, and momentum fluxes through the ocean surface form a crucial component of the Earth's climate system.

Having defined the various fluxes and their order of magnitude, this article will review methods of flux measurement and the sources of flux data. The regional and seasonal variation of the fluxes will be summarized. Following a discussion of the accuracy of our present flux estimates, the potential for future improvements will be considered.

Definition of the Fluxes

The momentum flux is the downward transfer of horizontal momentum caused by the drag of the sea surface on the wind. The wave-covered sea surface is continually in motion and, compared with typical land surfaces, appears remarkably smooth to the air flow. For gale force winds the waves may be 10 m or more in height, but the momentum flux is no more than that which would occur over a flat plain. As a result, wind speeds over the ocean tend to be greater than those over land.

The total heat transfer through the ocean surface, the net heat flux, is a combination of several components. The *shortwave radiative flux* (wavelength 0.3–3 μm) is the heat input from the Sun. Around noon on a sunny day this flux may reach about 1000 W m^{-2} but, when averaged over 24 hours, a typical value is 100–300 W m^{-2} , varying with latitude and season. Depending on the solar elevation and the sea state, about 6% of the incident radiation is reflected from the sea surface. Most of the remainder is absorbed in the upper few meters of the ocean. In calm weather, with winds less than about 3 m s^{-1} , a shallow layer may form during the day in which the sea has been warmed by a few degrees Celsius (a 'diurnal thermocline'). However, under stronger winds or at night the absorbed heat becomes mixed down through several tens of meters. Thus, in

contrast to land areas, the typical day to night variation in sea and air temperatures is small, typically less than 1°C. Both the sea and the sky emit and absorb long-wave radiative energy (wavelength 3–50 μm). Because, under most circumstances, the radiative temperature of the sky is colder than that of the sea, the downward long-wave flux is usually smaller than the upward flux. Hence the *net longwave flux* acts to cool the sea surface, typically by 30 W m^{-2} (if cloudy) to 80 W m^{-2} (clear skies).

The turbulent fluxes of sensible and latent heat also typically transfer heat from sea to air. The sensible heat flux is the transfer of heat caused by the difference in temperature between the sea and the air. Over much of the ocean this flux cools the sea by perhaps 10–20 W m^{-2} . However, where cold wintertime continental air flows over warm ocean currents, for example, the Gulf Stream region off the eastern seaboard of North America, the sensible heat flux may reach 100 W m^{-2} . Conversely, in regions like the summertime North Pacific Ocean, warm winds blowing over a colder ocean may result in a small sensible heat flux into the ocean. Under most weather conditions the evaporation of water vapor from the sea surface results in a water vapor flux from the sea to the air. The latent heat flux is the heat absorbed on vaporization of the water. This heat is released to warm the atmosphere when the vapor condenses to form clouds. Usually the latent heat flux is significantly greater than the sensible heat flux, being on average 100 W m^{-2} or more over large areas of the ocean. Over regions such as the Gulf Stream, latent heat fluxes of several hundred W m^{-2} are observed. In foggy conditions, with the air warmer than the sea, condensation may occur on the sea surface, and the vapor flux and latent heat flux are directed from air to sea. In summertime over the fog-shrouded Grand Banks off Newfoundland, the mean monthly latent heat transfer is directed into the ocean, but this is a very exceptional case.

Measuring the Fluxes

For the radiative fluxes, the standard method is to measure the voltage generated by a thermopile exposed to the incident radiation. A pyranometer, mounted in gimbals for use on a ship or buoy, is used to measure the incoming shortwave radiation (*Figure 1*). For better accuracy the direct and diffuse components should be determined separately but at present this is rarely done over the sea. The reflected short-wave radiation is normally calculated using tabulated values of the albedo for different solar elevations. Pyrgeometers, used for longwave radiation, are similar to pyranometers but have a coated dome to filter out the shortwave radiation. For these the use of gimbals is less important, but a clear sky view is required and corrections for the dome temperature and short wave leakage are needed. Again, only the downward component is normally measured; the upward component is calculated from the temperature and the emissivity of the sea surface.

Figure 1 A pyranometer used for measuring short-wave radiation. The thermopile is covered by two transparent domes. Photograph courtesy of Southampton Oceanography Centre.

The turbulent fluxes may be measured directly in the near surface atmosphere using the eddy correlation method. For example, if upward-moving air in the turbulent eddies is on average warmer and moister than the downward-moving air, then there is an upward flux of sensible heat and water vapor and hence also of latent heat. Similarly, the momentum flux may be determined from the correlation between horizontal and vertical wind fluctuations. Accurate eddy correlation measurements over the ocean are difficult. Since a large range of eddy sizes may contribute to the flux, fast-response sensors capable of sampling at 10 Hz or more must be exposed for periods of order 30 minutes for each flux determination. For instrumentation mounted on a buoy or ship the six components of the wave-induced motion must be measured and removed in the signal processing procedure. The distortion both of the turbulence and of the mean wind by ship, buoy, or fixed tower must be minimized and, if possible, corrected for. While three-component ultrasonic anemometers (Figure 2) are relatively robust, the sensors for measuring fluctuations in temperature and humidity have previously been fragile and, in the marine atmosphere, prone to contamination by salt particles and sea spray. Improved sonic thermometry, and water vapor instruments using microwave refractometry or differential infrared absorption, are relatively recent developments. Thus eddy correlation measurements are not routinely obtained over the ocean; rather they are used in air–sea interaction experiments to calibrate other flux estimation methods.

In the inertial dissipation method, fluctuations of the wind, temperature, or humidity at a few hertz are measured and related, through turbulence theory, to the fluxes. This method is less sensitive to flow distortion or platform motion but relies on various assumptions regarding the formation and dissipation of turbulent quantities that may not always be valid. It has been implemented on some research ships to increase the range of available flux data.

The bulk (aerodynamic) formulas are the most commonly used method of flux estimation. The flux is determined from the difference between the temperature, humidity or wind at some measurement height, z , and the value assumed to exist at the sea surface – respectively the sea surface temperature, 98% saturation humidity (to allow for salinity effects), and zero wind (or any non-wind-induced water current). Thus the flux F_x

Figure 2 The sensing head of a three-component ultrasonic anemometer. The wind components are determined from the different times taken for sound pulses to travel in either direction between the six ceramic transducers. Photograph courtesy of Southampton Oceanography Centre.

of some quantity x is given by eqn [1], where ρ is the air density and U_z is the wind speed at the measurement height.

$$F_x = \rho U_z C_{xz} (x_z - x_0) \quad [1]$$

While appearing intuitively correct (for example, blowing over a hot drink will cool it faster) these formulas can also be derived from turbulence theory. The value for the transfer coefficient, C_{xz} , characterizes both the surface roughness applicable to x and the relationship between F_x and the vertical profile of x . The transfer coefficient varies with the atmospheric stability, which itself depends on the momentum, sensible heat, and water vapor fluxes as well as the measurement height. Thus, although it may appear simple, eqn must be solved by iteration, initialized using the equivalent neutral value of C_{xz} at some standard height (normally 10 m), C_{x10n} . Typical neutral values are shown in Table 1.

Many research problems remain. For example: the increase of C_{D10n} at higher wind speeds must depend on the varying sea state, but can the latter be successfully characterized by the ratio of the predominant wave speed to the wind speed (the wave age), or by factors like the wave height and steepness, or is a complete spectral representation of the wave field required? What are the effects of waves propagating from other regions at varying angles to the wind (i.e., swell waves)? What is the exact behaviour of C_{D10n} in low wind speed conditions? Since C_{E10n} and C_{H10n} are not well defined by the available experimental

Table 1 Typical values (with estimated uncertainties) for the transfer coefficients. Neither the low wind speed formula for C_{D10n} nor the wind speed below which it should be applied, are well defined by the available, very scattered, experimental data. It should be taken simply as an indication that, at low wind speeds, the surface roughness increases as the wind speed decreases

Flux	Transfer coefficient	Typical values
Momentum	Drag coefficient, C_{D10n}	$0.61 (\pm 0.05) + 0.063 (\pm 0.005) U_{10n} (U_{10n} > 3 \text{ ms}^{-1})$ $0.61 + 0.57/U_{10n} (U_{10n} < 3 \text{ ms}^{-1})$
Sensible heat	Stanton no., C_{H10n}	$1.1 (\pm 0.2) \times 10^{-3}$
Latent heat	Dalton number, C_{E10n}	$1.2 (\pm 0.1) \times 10^{-3}$

data, recent implementations of the bulk algorithms have used theoretical models of the ocean surface (known as surface renewal theory) to predict these quantities from the momentum roughness length.

Sources of Flux Data

Until recent years the only routinely available sources of data were the weather reports from merchant ships. Organized as part of the World Weather Watch system of the World Meteorological Organization, these voluntary observing ships (VOS) are asked to transmit coded weather messages at 00.00, 06.00, 12.00 and 18.00 GMT daily, and to record a more detailed observation in a weather logbook. The very basic instruments used normally include a barometer and a means of measuring air temperature and humidity: wet and dry bulb thermometers mounted in a hand-swung sling psychrometer or in a fixed, louvered Stevenson screen. Sea temperature is obtained using a thermometer and an insulated bucket, or by reading the temperature of the engine cooling water intake. Depending on which country recruited the VOS, an anemometer and wind vane might be provided, or the ship's officers might be asked to estimate the wind velocity from the sea state using a tabulated Beaufort scale. Because of the problems of adequately siting an anemometer and maintaining its calibration, these visual estimates are not necessarily considered inferior to anemometer-based values.

The bulk formulas are used to calculate the turbulent fluxes from the VOS observations. However, in many cases the accuracy is poor. In particular, a large ship can produce significant changes in the local temperature and wind flow. The radiative fluxes must be estimated from the observer's estimate of the cloud amount plus, for short wave, the solar elevation, or for long wave, the sea and air temperature and humidity. The unavoidable observational errors and the crude form of the radiative flux formulas imply that large numbers of reports are needed, and correction schemes must be applied, before satisfactory flux estimates can be obtained. Though there are presently nearly 7000 VOS, they tend to be concentrated in the main shipping lanes. While coverage over most of the North Atlantic and North Pacific is adequate to provide monthly mean flux values, elsewhere data is mainly restricted to relatively narrow, major trade routes. For most of the Southern Hemisphere the VOS data are only capable of providing useful values if averaged over several years, and reports from the Southern Ocean are very few indeed. These problems must be borne in mind when studying the flux distribution maps

shown in marine climatological atlases, of which examples are presented below.

Satellite-borne sensors can overcome these sampling problems. 'Passive' sensors measure the radiation emitted from the sea surface and the intervening atmosphere at visible, infrared, or microwave frequencies; 'active' sensors transmit microwave radiation and measure the returned signal. The problem is to develop methods of determining the fluxes from the various satellite data that can be obtained. For example, sea surface temperature has been routinely determined using visible and infrared radiometers since about 1980. However, the data must be frequently checked against ship and buoy values to avoid errors due to changes in atmospheric aerosol content that may follow volcanic eruptions. Satellite-derived fields of net surface shortwave radiation are available; values for the net surface longwave radiation are less accurate. The surface wind velocity can be determined to good accuracy by active scatterometer sensors by measuring the microwave radiation back-scattered from the sea surface. The determination of near-surface air temperature and humidity from satellites is hindered by the relatively coarse vertical resolution of the retrieved data. Thus the radiation emitted by the near-surface air is dominated by that originating from the sea surface. Statistically based algorithms for determining the near-surface humidity have been successfully developed. More recently, neural network techniques have been applied to retrieving both air temperature and humidity; however, there is presently no routinely available product. Thus the satellite flux products for which useful accuracy has been demonstrated on a global basis are presently limited to momentum, short-wave radiation, and latent heat flux.

Numerical weather prediction (NWP) models (as used in weather forecasting centers) estimate values of the air-sea fluxes as part of the calculations. Assimilating much of the available data from the World Weather Watch system, including satellite data, radiosonde profiles, and surface observations, NWP models are potentially the best source of flux data. However, there are a number of problems. The vertical resolution of these models is relatively poor and many of the near-surface processes have to be represented in terms of larger-scale parameters. Improvements to NWP models are judged on the resulting quality of the weather forecasts, not on the accuracy of the surface fluxes, which may become worse. Indeed, the continual introduction of model changes results in time discontinuities in the output variables. Thus the determination of interannual variations is difficult and, for that reason, centers such as the European Centre for Medium Range Weather Forecasting (ECMWF) and the US National Centers for Environmental Prediction (NCEP) have recently reanalyzed the past weather

over several decades. The surface fluxes from these reanalyses are receiving much study. Those presently available appear less accurate than fluxes derived from VOS data in regions where there are many VOS reports; in sparsely sampled regions the model fluxes are more accurate. Particular weaknesses for the models are in the shortwave radiation and latent heat fluxes. New reanalyses are underway and efforts are being made to improve the flux estimates; eventually these reanalyses will provide the best source of flux data for many purposes.

The Regional and Seasonal Variation of the Momentum Flux

The main features of the wind regimes over the global oceans have long been recognized and descriptions are available in

many books on marine meteorology. The major features of the wind stress variability derived from ship observations from the period 1980 to 1993 are summarized here, using plots for January and July to illustrate the seasonal variation (Figure 3).

In Northern Hemisphere winter (Figure 3(a)) large wind stresses due to strong mid-latitude westerly winds occur in the North Atlantic and the North Pacific west of Japan. To the south, the extratropical high-pressure zones result in low wind stress values, and south of these is the belt of north-east trade winds. The very light winds of the Intertropical Convergence Zone (ITCZ) lie close to the Equator in both oceans. In the summertime Southern Hemisphere the south-east trade wind belt is less pronounced. The extratropical high-pressure regions are extensive but, despite it being summer, high winds and significant wind stress exist in the mid-latitude Southern

Figure 3 Monthly vector mean wind stress (N m^{-2}) for (a) January and (b) July calculated from voluntary observing ship weather reports for the period 1980 to 1993. Adapted from Josey SA, Kent EC, and Taylor PK (1998). The Southampton Oceanography Centre (SOC) Ocean–Atmosphere Heat, Momentum and Freshwater Flux Atlas, SOC Report No. 6.

Ocean. The north-east monsoon dominates the wind patterns in the Indian Ocean and the South China Sea (where it is particularly strong). In the latter regions the ITCZ is a diffuse area south of the Equator with relatively strong south-east trade winds in the eastern Indian Ocean.

In Northern Hemisphere summer (Figure 3(b)) the wind stresses in the mid-latitude westerlies are very much decreased. Both the north-east and the south-east trade wind zones are evident respectively to the north and south of the ITCZ, which mainly lies north of the Equator. The south-east trades are particularly strong in the Indian Ocean and feed air across the Equator into a very strong south-westerly monsoon flow in the Arabian Sea. These ship data indicate very strong winds in the Southern Ocean south-west of Australia. Such winds are also evident in satellite scatterometer data, which suggest that the winds in the Pacific sector of the Southern Ocean, while still strong, are somewhat less than those in the Indian Ocean sector. In contrast, the ship data appear to show light winds. The reason is that in wintertime there are practically no VOS observations in the far South Pacific. The analysis technique used to fill in the data gaps has, for want of other information, spread the light winds of the extratropical high-pressure region farther south than is realistic; this is a good example of the care needed in interpreting the flux maps available in many atlases.

The Regional and Seasonal Variation of the Heat Fluxes

The global distribution of the mean annual net heat flux is shown in Figure 4(a). Averaged over the year, the ocean is heated in equatorial regions and loses heat in higher latitudes, particularly in the North Atlantic. However, this mean distribution is somewhat misleading as the plots for January (Figure 4(b)) and July (Figure 4(c)) illustrate. The ocean loses heat over most of the extratropical winter hemisphere and gains heat in the extratropical summer hemisphere. It is only because the tropical oceans are heated throughout the year, and atmospheric moisture from trade wind zones converges in the ITCZ, that the tropics are so important with regard to driving the atmospheric circulation. The major regions of ocean cooling occur in winter over the Gulf Stream and the Kuroshio currents. However, in summer the long period of day-light in these mid-latitude regions results in mean short-wave radiation values similar to or larger than those observed in equatorial regions. Thus the mean monthly short-wave flux is greater than the cooling induced by the combined latent heat and net long-wave fluxes. At a more typical mid-latitude site the ocean cools in winter and warms in summer, in each case by around 100 W m^{-2} . The annual mean flux is small, of order 10 W m^{-2} , but cannot be neglected because of the very large ocean areas involved.

Considering now the interannual variation of the surface fluxes, the major large-scale feature over the global ocean is the El Niño Southern Oscillation system in the equatorial Pacific Ocean. In the eastern equatorial Pacific the change in the net heat flux under El Niño conditions is around 40 W m^{-2} . For extratropical and mid-latitude regions the interannual variability of the summertime net heat flux is typically

about $20\text{--}30 \text{ W m}^{-2}$, being dominated by the variations in latent heat flux. In winter the typical variability increases to about $30\text{--}40 \text{ W m}^{-2}$, although in particular areas (such as over the Gulf Stream) variations of up to 100 W m^{-2} may occur. The major spatial pattern of interannual variability in the North Atlantic is known as the North Atlantic Oscillation (NAO). This represents a measure of the degree to which mobile depressions, or alternatively near-stationary high-pressure systems, occur in the mid-latitude westerly zone.

Discussion: Accuracy of Flux Estimates and Future Trends

We have seen that, although the individual flux components are of the order of hundreds of W m^{-2} , the net heat flux and its interannual variability over much of the world ocean is of the order of tens of W m^{-2} . Furthermore, it can be shown that a flux of 10 W m^{-2} over one year would, if stored in the top 500 m of the ocean, heat that entire layer by about 0.15°C . Temperature changes on a decadal time scale are at most a few tenths of a degree, so the global mean budget must balance to better than a few W m^{-2} . For these various reasons there is a need to measure the flux components, which vary on many time and space scales, to an accuracy of a few W m^{-2} . Given the available data sources and methods of determining the fluxes described above, it is not surprising that this accuracy at present cannot be achieved.

To take an example, in calculating the flux maps shown in Figure 4 many corrections were applied to the VOS observations in an attempt to remove biases caused by the observing methods. For example, air temperature measurements were corrected for the 'heat island' caused by the ship heating up in sunny, low-wind conditions. The wind speeds were adjusted depending on the anemometer heights on different ships. Corrections were applied to sea temperatures calculated from engine room intake data. Despite these and other corrections, the global annual mean flux showed about 30 W m^{-2} excess heating of the ocean. Previous climatologies calculated from ship data had shown similar biases and the fluxes had been adjusted to remove the bias, or to make the fluxes compatible with estimates of the meridional heat transport in the ocean. However, comparison of the unadjusted flux data with accurate data from air-sea interaction buoys showed good agreement between the two. This suggests that adjusting the fluxes globally is not correct and that regional flux adjustments are required; however, the exact form of these corrections is presently not known.

In the future, computer models are expected to provide a major advance in flux estimation. Recently, coupled numerical models of the ocean and of the atmosphere have been run for many simulated years, during which the modeled climate has not drifted. This suggests that the air-sea fluxes calculated by the models are in balance with the simulated oceanic and atmospheric heat transports. However, it does not imply that at present the flux values are realistic. Errors in the short-wave and latent heat fluxes may compensate one another; indeed, in a typical simulation the sea surface temperature stabilized to a value that was, over large regions of the ocean, a few degrees different from that

Figure 4 Variation of the net heat flux over the ocean; positive values indicate heat entering the ocean: (a) annual mean; (b) January monthly mean; (c) July monthly mean. which is observed. Nevertheless, the estimation of flux values using climate or NWP models is a rapidly developing field and improvements will doubtless have occurred by the time this article has been published. There will be a continued need for in-situ and satellite data for assimilation into the models and for model development and verification. However, it seems very likely that in future the

most accurate routine source of air–sea flux estimates will be from numerical models of the coupled ocean–atmosphere system.

Sea Surface Temperature

WJ Emery, University of Colorado, Boulder, CO, USA

Synopsis

Sea surface temperature (SST) is the interface between the ocean and the overlying atmosphere. As such, it controls the exchange of heat and gases between the atmosphere and ocean. It is also the longest and most widely measured parameter in the ocean. Traditionally measured by inserting a mercury-in-glass thermometer in a bucket sample of surface water from a sailing ship or from a coastal observing station, it is now widely directly measured by drifting and moored buoys or from engine-cooling water on ships. The need for global SST observations has driven the use of infrared satellite data to estimate SST, which has now extended to the use of passive microwave data as well. The satellite measurements distinguish themselves from the in situ measurements in that they measure the skin of the ocean rather than the subsurface 'bulk' SST measured by ships and buoys.

Introduction

As the controlling variable of heat, momentum, salt, and gas fluxes between the ocean and the atmosphere, the sea surface temperature (SST) has always been a topic of interest to scientists. It is also the easiest oceanographic parameter to observe, and observations of some form of SST extend back to the time of the early Greek scientists. In addition to its relationship to ocean-atmosphere fluxes, the SST also relates directly to a number of human concerns. For example, the success of fisheries and fishermen can be enhanced by knowledge of the SST pattern. For many years, SST was measured by taking a 'bucket sample' of the surface waters and then measuring its temperature. As ships evolved to powered vessels, this practice of SST bucket sampling had to be abandoned, and the practice of using measurements of the temperature of the cooling water coming to the ship's engines was used. These were known as 'ship injection temperatures' (as the SST sensor was 'injected' into the water stream), and these data suffer from many basic problems (engine room heating, depth of the water intake, etc.). The advent of satellite-tracked drifting buoys introduced a platform that could measure the SST and then report it in near-real time. Thought to be less noisy and more accurate than ship SSTs, the drifting buoy SST data became the standard for both the calibration and validation of satellite infrared estimates of SST. Over the years, these buoy SSTs have been used to calculate the infrared algorithm coefficients for the computation of the SST. The problem is that a buoy cannot measure the temperature of the 10 μm thin 'skin of the ocean,' which is the layer that radiates out into space. Thus, satellite infrared measurements of SST are of this skin temperature and not of the deeper bulk SST measured by the ships and buoys. It is the difference between the skin and bulk temperature that is directly related to the wind speed and the net air-sea heat flux. In the past, the bulk SST has been used in the computation of air-sea heat flux terms using empirical 'bulk' formulas. These continue to be used, but research efforts are underway to transform these computations into a satellite-only calculation. These efforts will explicitly involve skin and bulk SSTs, giving a more physical basis to the connections between heat flux and the skin and bulk SSTs. These improvements are critical for the modeling of climate change, since the SST is the boundary that

connects the model atmosphere to the model ocean. Any incorrect specification of the global SST patterns will lead directly to errors in the model simulations.

History of SST Measurements and Applications

One of the earliest uses of SST was when Benjamin Franklin mapped the position of the Gulf Stream from SST measurements made from the mail packet ships that he rode to and from Europe. Fortunately for Franklin, the Gulf Stream has a very sharp thermal contrast on its western edge, where the cold shelf waters coming from the north meet the warm Gulf Stream waters advecting to the northeast. Together with Timothy Folger, he published a map ([Figure 1](#)) that described the position of the Gulf Stream, advising ship captains not to sail against this current, which was strong enough to hold a sailing vessel still. This practical application of SST made it possible to reduce the crossing times for ships sailing from the Americas to Europe.

As one of the easiest measurements in oceanography, SST became widely observed, whether as a sample taken from a pier or beach or as a bucket sample from a ship on the open ocean. The collection of a bucket of water whose temperature was measured as an estimate of SST became common practice among the sailing ships carrying the world's commerce. When the ships' logs became the source of global information on winds and currents, the SST information was also compiled from the ships' logs. This information was routinely published, along with the currents and winds from the ships' logs, as part of 'sailing directions' put out first by the US Navy and later by the US Coast Guard. The same practice was introduced later in Europe and became an operational reality for most oceangoing vessels.

The collection of a bucket sample from sailing ships that travel at speeds between 5 and 15 knots was easy. For powered ships traveling at 20–30 knots, it was no longer possible to collect a bucket sample for SST measurement. Instead, the temperature of the water used to cool the ship's engines was measured as the SST. This temperature was called the 'injection' temperature because, as mentioned in the Introduction, the sensor was 'injected' into the pipe carrying this cooling water to

Figure 1 The Poupard version of the Franklin–Folger Gulf Stream chart published in Philadelphia in 1786 with Franklin's *Maritime Observations*.

the heat exchangers. One of the fundamental problems with these injection temperatures was the location of the inlet pipe for this cooling water, which was positioned far down the ship's hull, generally collecting water from about 5 m depth – far away from the sea surface. In addition, the heat in the engine room was known to heat the cooling water and the associated thermometer, resulting in a warm bias for the SSTs. Other sources of error were the reading of the analog gauge, the hand recording of the data in the ship's log, and the radio broadcast of the 'SST' to be included in the SST database.

Satellite SST

In spite of all these limitations, ship SSTs were initially used to match and adjust infrared satellite measurements of the SST. Later, satellite-tracked drifting buoys were equipped with temperature ports sticking out from the hull to measure the SST as the buoy traveled around the ocean. Most of these buoy SST sensors were initially calibrated to $\pm 0.1^\circ\text{C}$, but since the buoys are considered expendable there is no postdeployment calibration, and it is not known how well the buoys retain their calibration. There are about three different hull types used today in these buoys, with slightly different configurations of the hull SST sensors. All of these buoys float in the active near-surface layer and move up and down with the wave field. As a consequence, the buoy SST represents the temperature between the surface and 1–2 m depth. The best estimate of the accuracy of these data can be made by considering the mean

difference and variability of the difference between contemporary SST measurements. This value is 0.4°C , which can be taken as an overall error limit for buoy-measured bulk SST.

It is important to realize that past practice has been to compute the satellite infrared SST algorithm coefficients from regression with nearly coincident buoy SST data. In this approach, one assumes not only that the satellite and buoys measure the same SST, but also that the buoy SSTs have no errors themselves. That is not to say that people assume the buoy SSTs have no error, but the practice of using them to find the algorithm coefficients through linear regression implies that the buoy SSTs are error-free. It appears that the source of this conflict is the fact that satellite infrared systems and their calibration systems do not retain their calibrations over long periods of time and that regression to in situ SST is required to overcome these drifts. Since buoy SSTs are the best of the present in situ SSTs, they are used to supply the in situ SST observations in spite of the fact that they do not and cannot measure the skin SST, as any direct physical contact with the skin layer will temporarily disrupt it. Observations of the effects of breaking waves on the presence of the skin layer have shown that while a breaking wave does indeed destroy the skin layer, the skin forms again after just a few seconds. So, in spite of strong winds and breaking waves, the skin SST layer is present most of the time and must be considered in the remote sensing of SST. Before various groups and agencies will transform their computations to skin SST, there must be a source of in situ skin SST to replace the buoy SSTs that are used at present. We will discuss this point further in this article.

SST Climatology

One of the benefits of being relatively easy to observe is the abundance of data that exists both geographically and over time. This excellent data coverage makes it possible to compute a climatology of SST conditions, which is a long-term average map of SST conditions (usually over the 12-month period of an annual cycle). Many different climatologies have been computed for SST, starting with strictly ship measurements before about 1970 and followed by a mix of satellite, ship, and buoy SSTs since then. One must always be careful to determine exactly which periods are covered by such a climatology and what data went into the computation of the climatology.

For this article, we will use a climatology that includes satellite infrared, buoy, and ship SST data. As part of this analysis, satellite SSTs were filtered to eliminate obvious outliers. The input buoy and ship SST data sets were also filtered to remove large errors. All three of these input data sets were to save space. We only present four images to represent the 12-month annual cycle. The first is a global map of SST for the month of January (**Figure 2**), which represents SST conditions for the Northern Hemisphere winter.

In this map, a number of basic features are readily obvious. The warmest temperatures are in the tropics, particularly in the Pacific and Indian Oceans; the warmest temperatures are found in the 'warm pool' of the western tropical Pacific. There are cold features along the west coasts of South America and South Africa, which correspond to upwelling events most active in the

austral summer. Cold temperatures extend a bit farther north in the Southern Ocean than they do in the Northern Hemisphere, which is primarily a consequence of the open character of the Southern Ocean compared with the geographically restricted waters of the Arctic.

The representative Northern Hemisphere spring SST map in **Figure 3** shows a modest shift in this temperature distribution. The warmest temperatures have increased, particularly in the equatorial Indian Ocean, which has increased from about 28 °C to about 30 °C. The Western Pacific Warm Pool has expanded slightly and increased in temperature. There is now a distinct band of warm temperatures in the equatorial Pacific. The upwelling zones off southwestern South America and South Africa have decreased in size. The colder SSTs have remained largely the same.

Turning to the Northern Hemisphere summer, we look at the July SST climatology in **Figure 4**. In this case, the maximum temperatures in the tropics have actually cooled slightly, reflecting the decrease in solar insolation on a global level. The warm band in the tropical Atlantic has weakened, as has the equatorial warm band in the tropical Indian Ocean. Even the warm pool in the western tropical Pacific has weakened in both magnitude and areal coverage. The upwelling zones off western South America and western South Africa have again expanded, and both show warm tongues that extend westward from the northernmost extent of the colder upwelling water. There is a corresponding cold upwelling region off North America consistent with the seasonal shift to northerly upwelling winds off that coast. The same is true off northwest Africa.

Figure 3 April SST climatology. Reproduced with permission from Reynolds, R.W., Smith, T.M., 1995. A high resolution global sea surface temperature climatology. *Journal of Climate* 8, 1571–1583.

Figure 4 Mean July SST. Reproduced with permission from Reynolds, R.W., Smith, T.M., 1995. A high resolution global sea surface temperature climatology. *Journal of Climate* 8, 1571–1583.

Figure 5 Mean October SST. Reproduced with permission from Reynolds, R.W., Smith, T.M., 1995. A high resolution global sea surface temperature climatology. *Journal of Climate* 8, 1571–1583.

To complete the cycle, we look at the Northern Hemisphere fall (October) map in [Figure 5](#). In this map, all of the west coast upwelling regions have weakened slightly. In particular, the upwelling region of northwest Africa has disappeared. In the Southern Hemisphere, the upwelling regions appear to have stretched farther to the west. The equatorial warm regions have weakened in magnitude, although they are about the same in geographic coverage as they were in July. The colder waters have not changed much since the last season (summer).

All of these maps have used a mixture of satellite infrared measurements, drifting and moored buoy SST measurements, and ship SST measurements. In this application, the satellite skin SST is adjusted to match coincident drifting buoy SSTs, as introduced in this article. Thus, these maps really represent a ‘pseudobulk SST’ due to the overwhelming number of infrared SST observations as compared to the in situ buoy and ship observations. Still, the general seasonal pattern of the SST is clearly apparent, and it is not likely that an adjustment to skin SST would show any substantially different SST patterns. SST patterns computed from various satellite SST algorithms all look very similar; it is the absolute temperature value that is different, and the skin SST must be considered when addressing questions such as air–sea heat and gas exchange.

Skin SST

Due to its very high emissivity, the ocean is considered to very nearly approximate a ‘blackbody.’ This long-wave heat emission

is directly proportional to the skin SST, which is the only SST that interacts with the overlying atmosphere. Having a thickness of between 5 and 10 μm , the skin of the ocean can easily be destroyed by breaking ocean waves. When this happens, the skin reforms within 3–6 s, which means that the skin of the ocean is most generally present. This skin layer is the molecular boundary between the turbulent atmosphere and the turbulent ocean. It is this skin layer that transfers heat, gases, and momentum between the atmosphere and the ocean. The temperature of this ultrathin layer can be measured only radiometrically, since any contact with the skin layer will disturb it. Thus, this layer cannot be measured directly by drifting or moored buoys or by any ship. Equipped with infrared radiometers, ships could measure this skin layer temperature radiometrically without the attenuating atmosphere in between the ship radiometer and the sea surface. Such measurements could provide validation and possibly calibration information for satellite-based infrared radiometric measurements of skin SST.

An important question is ‘What is the precise definition of bulk SST?’ Drifting buoys measure a temperature somewhere between 0.5 and 1.5 m below the sea surface. This is a result of the buoy’s interaction with the waves at the sea surface. As described in this article, ship cooling water intake ports may be located anywhere from 2 to 5 m beneath the waterline. So is the bulk SST located at 2–5 m beneath the surface? If we consider the temperature profile in the shallow upper layer of the ocean ([Figure 6](#)), we can see that the skin SST is always slightly colder than the

Figure 6 Temperature profile in the shallow upper layer of the ocean.

temperature just below it. Note the logarithmic abscissa in this plot. At night, this temperature slightly below the cooling skin layer is isothermal to a depth of a few meters. In this case, the bulk temperature could be measured at any of the depths to 5 m. During the day, however, solar insolation can heat a shallow layer sufficiently so that the temperature of the ‘cool skin’ is a little higher than the isothermal layer below the warm diurnal layer. Often referred to as ‘warm-skin SST,’ this condition can exist only during daytime under relatively clear-sky conditions when the shallow surface layer is heating.

The relationship between the skin and the bulk temperatures depends on two forcing factors: the wind and the net air-sea heat flux. A good example of this is shown in **Figure 7**, which is taken from two different oceanographic research cruises. Here, we have plotted the difference between the skin SST and the bulk temperature (taken as a temperature at a depth between 2 and 5 m) as a function of wind speed and net air-sea heat flux. The wind speed was observed from the research vessel, while the net air-sea heat flux was calculated from the traditional bulk formulas using routine meteorological measurements also made from the ship. At the top is a series from a cruise on the FS Meteor in the North Atlantic. Here, interestingly enough, the ΔT between the skin SST and the bulk temperature both rises and falls with increasing wind speed. At low heat flux levels, ΔT decreases as wind speed increases. This is consistent with traditional wisdom that increased mixing due to wind stirring will homogenize the upper layer, eventually making skin and bulk temperatures the same. At higher heat flux values, however, ΔT actually increases as the wind speed increases. In the lower figure, a data set was collected from the tropical Pacific. A much more limited change in ΔT is found for this tropical sample, but there is still a decrease in ΔT with increasing wind.

Figure 7 Skin and bulk temperatures as a function of wind speed and net air-sea heat flux.

These effects can be modeled with a semiempirical formula that includes the effects of wind and net heat flux on the ΔT difference between skin SST and bulk temperature:

$$\Delta T = \frac{Q_N}{\rho_w c_p \kappa^{1/2}} \left\{ C_{\text{shear}} \left(\frac{\nu Z_0}{u^{*3}} \right)^{1/2} + \left[C_{\text{conv}} \left(\frac{\nu \rho_w c_p}{\alpha g Q_N} \right)^{1/2} - C_{\text{shear}} \left(\frac{\nu Z_0}{u^{*3}} \right)^{1/2} \right] e^{-Rf_{\text{cr}}/Rf_0} \right\}^{1/2} \quad [1]$$

where Q_N is the net heat flux, ρ_w is the density of water, c_p is the specific heat capacity of seawater at a constant pressure, κ is the thermal diffusivity of water, C_{shear} is the proportionality constant for shear-driven time scale, C_{conv} is the proportionality constant for convective-driven time scale, ν is the kinematic viscosity, Z_0 is the momentum roughness length, u^* is the friction velocity of water, g is the acceleration due to gravity, α is the thermal expansion coefficient, Rf_0 is the surface Richardson number, and Rf_{cr} is the critical Richardson number.

This equation connects the skin SST with the temperature just below it, but does not account for the further transfer of heat downward or upward within the water column. To do this, a ‘mixed-layer’ model must be added to the skin-bulk parametrization. Such a model has been employed to show the development of the full upper-layer temperature profile. Using this model combination, it was possible to trace the temperature history of the upper layer for a couple of consecutive days of field measurements. There is excellent agreement between

the observed bulk–skin (ΔT) temperature difference and that modeled using the wind speed and net air–sea heat flux. Thus, it appears that this combination of models can go a long way to simulating the temperature behavior of the upper layer of the ocean. It should be noted that these models do not account for surface wave effects, or the effects of turbidity and foam on the sea surface. It is likely that these effects are smaller in magnitude than those driven by the wind and net heat flux. Much more sophisticated models will be required to include these phenomena in modeling ΔT .

In Situ Measurement of Skin SST

Since infrared satellite sensors are able to measure radiation only from the skin of the ocean, the challenge is to provide in situ measurements of the skin SST that can be used to calibrate and validate the satellite radiances in terms of temperature. As mentioned in this article, ships can be equipped with radiometers to measure directly the skin SST without the atmosphere attenuating the infrared signal. In principle, these same radiometers could be installed on moored buoys to continuously measure skin SST. The problem with both of these installations is that the radiometer optics must be protected from sea spray, which is difficult to do in an autonomous installation. At least on the ship, the radiometer can be examined each day and cleaned off to maintain a clear optical path.

Another requirement of these radiometers is that they are very well calibrated. The best approach to fulfilling this requirement is to equip the radiometers with two blackbodies, one at ambient temperature and the other is heated about 10 degrees above ambient. To correct for reflected infrared sky radiation, these radiometers must look up and down to view the sky, the ocean, and both blackbodies for every few scans. The easiest way to implement these requirements is to use a rotating mirror to channel the radiation to the detector, as

seen in Figure 8. In this setup, the sensor is a low-cost thermal infrared ‘microbolometer’ with a supplemental rotating mirror to collect radiation from the sky through the top hole, the sea surface through the bottom hole, and both of the blackbodies to the sides. The microbolometer collects 2D array thermal infrared image that is then calibrated regularly by the onboard blackbodies.

It is difficult to predict just how many ships need to be operating to provide the global coverage needed to regularly calibrate and validate the satellite radiometers. It is clear that the need for continuing sampling means that the ships must be merchant ships traveling long routes on a regular basis. A plot of the present ship coverage for a year (Figure 9) reveals that there are plenty of ships to choose from in the Northern Hemisphere, but in the Southern Hemisphere the available selection is much more restrictive. Ship tracks that make the long transits to Australia and New Zealand are good candidates, as are those routes from Asia to southern Chile. Only experience will reveal just how many ships over which routes will be required to supply the in situ skin SSTs needed to calibrate and validate the satellite infrared radiances.

Summary and Conclusions

SST is and has been one of the most measured variables in the ocean, and as such it has received much scientific attention. Using a combination of ship SSTs, moored and drifting buoy SSTs, and satellite infrared SSTs, we have characterized the global and seasonal patterns of SST. Realizing that only the satellite infrared SSTs can represent the SST of the 10 μm thick skin layer of the ocean, future efforts should be aimed at separating the satellite skin SSTs from the 1–5 m deep bulk SSTs measured by the buoys and ships. The skin layer is simply the molecular layer that interfaces between a turbulent ocean and a turbulent atmosphere. The temperature difference between the skin and the bulk temperatures is directly related to the wind

Figure 8 Modular microbolometer-based infrared radiometer (the ball experimental SST or BESST).

Figure 9 Global merchant ship routes for 1996.

speed and net air–sea heat flux. Thus, an improved understanding of this relationship can help us to better resolve the net heat and momentum fluxes between the ocean and the atmosphere. In part, this understanding and the shift to the computation of skin SST from satellite infrared data depend on the creation of a network of ‘ship of opportunity’ based skin SST radiometers collecting global and continuous samples of skin SST ‘ground truth’ data (i.e., without an intervening atmosphere).

Synopsis

Wind waves relate directly to interactions at the air–water interface that affect turbulent regimes in the atmospheric surface layer and the ocean’s upper layer and finally result in exchange of momentum, energy, heat, and moisture. The turbulent boundary layers around the air–sea interface and the interface itself are the unified dynamical system. The air–sea heat–mass–energy exchange is regulated by the turbulence of boundary layers around the air–sea interface. Part of the wind energy and momentum is transferred directly from atmosphere to drift currents, while another part goes into growing surface waves and ocean turbulence.

Introduction

The total area of the world ocean surface, including inner seas, is equal to $361 \times 10^3 \text{ km}^2$ that is 70.8% of the area of Earth surface. Most motions of the ocean water (apart from the tides, currents near estuaries, and the infrequent motions of water mass produced by tectonic or volcanic activities at the ocean floor) are the results of atmospheric impacts. In fact, the world ocean surface is permanently covered by surface waves associated with local wind conditions, and this affects all air–sea interaction processes. The thermal state of the ocean and the seawater stratification significantly depend on atmospheric influences. In particular, these influences are responsible for the strong hydrostatic stability of the ocean, and heating and cooling the ocean’s upper layer. The controlling influence of oceans, particularly in forming weather, is turbulence in the atmospheric and oceanic boundary layers and microinteraction of water and air flow in vicinity of their interface. The main manifestations of the air–sea interaction in the atmosphere are the long-term variability of weather and the formation of climate.

Wind waves relate directly to interactions at the air–water interface that affect turbulent regimes in the atmospheric surface layer and the ocean’s upper layer and finally result in exchange of momentum, energy, heat, and moisture. The character of this transport is regulated by the turbulence of boundary layers around the air–sea interface. These influences are very complex and still poorly understood, although there have been numerous experimental and theoretical investigations. There are not sufficient observational data to specify completely the quantitative impact of surface waves on the characteristics of air–sea boundary layers. One of the major difficulties in air–sea interaction problems is the correct description of surface-wave effects. Here, the distinctive feature is the oscillation of the air–water interface, so that the classical theory of wall turbulence is generally inapplicable.

Surface waves are the most visible manifestation of time-dependent ocean dynamics and have been of interest for as long as man has been involved in fishing, navigation, and trade. Surface waves are important components of the air–sea system. Part of the wind energy and momentum is transferred directly from atmosphere to drift currents, while another part

goes into growing surface waves. Surface waves are the ocean’s responses to wind and pressure changes at the air–sea interface. Surface waves include capillary waves, which undulate within a fraction of a second over a distance less than a centimeter and planetary waves with periods of years and wavelengths of thousands kilometers. For air–sea interaction, surface waves are more important and we will focus on wind-generated waves at the air–sea interface. These waves determine the small-scale configuration of the air–sea interface and that affects the turbulent transfer. These waves depend on the state of the upper layers of the ocean.

Surface waves have been studied actively theoretically and experimentally. Although waves have been studied a long time, existing theories have been able to predict ocean waves with acceptable accuracy not too long ago. Complicated nonlinear interactions between wind, waves, current, and turbulence make both theoretical and observational studies more difficult. Surface waves have relatively short periods, mostly within the range of 1–30 s. The surface waves that determine sea conditions in coastal regions and break on the shore may have been generated either in open ocean and traveled coastward or in the coastal region itself by local winds. The initial wave generation process is similar in the open ocean and coastal regions, but the shallower water depth begins to affect the waves when it is less than about half a wavelength. The longer waves are affected first when a spectrum of waves travels into shallow region. Currents such as tidal currents also affect waves and these currents are often stronger in coastal regions. The reflection of waves, due to the reduction in the velocity of propagation in coastal region, also has an important influence on the waves near the shore. The classical theory of surface waves deals with waves of uniform amplitude, wavelength, and period, traveling in a fixed direction. In reality, ocean surface waves have very different heights, periods, wavelengths, and characters. Surface waves are studied by defining average values (height, period, and wavelength), the distribution of values around mean value, and a wave spectrum, representing the actual sea surface as a superposition of a large number of waves with various periods, amplitudes, and directions.

Remote sensing has evolved such that many parameters of the ocean surface may now be measured. In terms of air–sea interactions the ocean parameters include surface currents, wave directional spectra, surface wind and heat flux, and

temperature. Atmospheric quantities include profiles of winds, temperature, humidity, and chemical species. The remote sensing of surface waves and fluxes has been based, in most part, on empirical fits of infrared and active remote sensing signatures to ground truth measurements. Microwave remote sensing has provoked an active interest in the shortest waves. Short gravity waves and capillary waves have recently received attention as the progenitors of the backscatter cross section observed by microwave remote sensors. The backscatter cross section is a measurement of the amount of microwave reflection from capillary and short gravity waves with wavelengths in the range 1–6 cm. On the smallest scales, the capillary waves and short gravity waves respond quickly to the wind, and thereby provide a linkage to the remote microwave sensors. Synthetic aperture radar provides high-resolution imagery of the sea surface by measuring Bragg scattered radar pulses from the sea surface.

Equation of Motion

The approximate conservation equations of momentum and mass may be written:

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} + f \cdot [\mathbf{n} \times \mathbf{u}] + \frac{\nabla p}{\rho} = \nu \Delta \mathbf{u} + \mathbf{g} + \mathbf{Fr}, \quad [1]$$

$$\nabla \cdot \mathbf{u} = 0. \quad [2]$$

Here, t is time, $\mathbf{u} = \{u_1, u_2, u_3\}$ is the velocity of wind in the atmospheric boundary layer or the velocity of ocean current in the oceanic boundary layer with the horizontal components u_1, u_2 and vertical u_3 , ∇ is the gradient operator, p is pressure, ρ is the density of air in the atmospheric boundary layer or the density of seawater in the oceanic boundary layer (in boundary layers around the air-sea interface the density variations $\delta\rho$, which is the air density variation $\delta\rho_a$ in the atmosphere and the seawater density variation $\delta\rho_w$ in the ocean, are very small regarding to the reference density $\rho_0 = (\rho_{0a}, \rho_{0w})$ with the air density $\rho_{0a} \approx 1.23 \text{ kg m}^{-3}$ at a pressure of 1013 hPa and a temperature of 15 °C, and the seawater density $\rho_{0w} \approx 1000 \text{ kg m}^{-3}$ at a pressure of 1013 hPa and a temperature of 15 °C, $|\delta\rho/\rho_0| \ll 1$), ν is the kinematic molecular viscosity (at a temperature $T = 20$ °C, $\nu = \nu_a = 1.5 \times 10^{-5} \text{ m}^2 \text{ s}^{-1}$ for air and $\nu = \nu_w = 1 \times 10^{-6} \text{ m}^2 \text{ s}^{-1}$ for the water), $\mathbf{g}$ is the gravitational acceleration ($|\mathbf{g}| = 9.81 \text{ m s}^{-2}$, the direction of $\mathbf{g}$ defines the local vertical), $f = 2\Omega \sin \phi$ is the Coriolis parameter (where $\Omega = 1.161 \times 10^{-5} \text{ Hz}$ is the angular velocity of rotation of the Earth and ϕ is latitude), $\mathbf{n}$ is the unit vector directed along the z -axis, ν is the kinematic viscosity of air or seawater consequently. The forcing term $\mathbf{Fr}$ with components $\text{Fr}_x, \text{Fr}_y, \text{Fr}_z$ represents any forces, other than pressure or gravity or viscous friction, acting in the body of the water. The momentum equations state that a change in the velocity following the motion of a water parcel is caused by an imbalance of the Coriolis force (rotation of the Earth), the force by the pressure gradient, the viscous forces, and the external forces. The assumption that the density element of fluid does not change (though it may differ for different elements) reduces the equation of mass conservation to the incompressibility condition [2], also known as the continuity equation, states that the divergence of the horizontal velocity must be balanced by vertical motion.

Surface Wave Dynamics

The Governing Equations

Surface wave theory assumes that the influences of Coriolis force, viscous friction and buoyancy on water motions are negligible, and that the wave motion is irrotational, i.e., there is no vorticity or the curl of the velocity vector is zero ($\text{curl} \mathbf{u} = 0$). A velocity potential φ is defined as $\mathbf{u} = \mathbf{v} = \nabla \varphi$, and from eqn [2], there follows Laplace's equation:

$$\Delta \varphi = 0. \quad [3]$$

At fixed surface, such as an impermeable seabed, the normal velocity component vanishes. The free surface is specified as $z = \zeta(x, y, t)$ at all times, then the kinematic free-surface condition follows:

$$w_\zeta = d\zeta/dt = (\partial\varphi/\partial z)_\zeta = \partial\zeta/\partial t + (\nabla_h \varphi)_\zeta \cdot (\nabla_h \zeta), \quad [4]$$

where $\nabla_h = (\partial/\partial x, \partial/\partial y)$ is the horizontal gradient operator, the suffix ζ indicates a quantity at the free-surface $\zeta(x, y, t)$. In this case, eqn [1] reduces to Bernoulli's equation, and then the pressure p in the water at the free surface is given by

$$\begin{aligned} p/\rho_w + g\zeta + (\partial\varphi/\partial t)_\zeta + 0.5(\nabla\varphi \cdot \nabla\varphi)_\zeta &= 0, \\ p &= p_{a0} - \gamma(\nabla_h \cdot \nabla_h)\zeta, \end{aligned} \quad [5]$$

where p_{a0} is the atmospheric pressure on the Earth's surface, and γ , in the term of the pressure by the water surface tension, is the ratio of surface tension to water density ($\gamma = 0.074 \text{ N m}^{-1}$ at $T = 15$ °C).

Small-Amplitude Waves

The approach of small-amplitude waves corresponds well to the real waves because the ratio of the wave amplitude a to the wavelength λ is small ($a/\lambda \ll 1$). In this case, nonlinear terms in eqns [4]–[5] will be negligible. At the surface, using kinematic boundary condition and boundary condition for pressure, solutions show that the water particles move in circular orbit of radius ae^{kz} where depth $z \leq 0$ and the wave number $k = 2\pi/\lambda$. The presence of a restoring force (gravity and surface tension) establishes a relationship between the wave frequency ω and the wave number vector $\mathbf{k}$ ($\mathbf{k} = (k_x, k_y)$) is directed along the direction of the wave propagation), which is known as a dispersion relation and, in the case of the wave propagation on the surface of a water layer of thickness H , is

$$\omega^2 = (gk + \gamma k^3/\rho_w) \tan h(kH). \quad [6]$$

The velocity of wave propagation, phase velocity, is defined by $c = \omega k/k^2$. The energy density is the energy of a wave field in a unit of volume, which is proportional to the mean square amplitude of all waves in the volume. Wave radiation is a transport or flux of energy that is caused by the waves. Surface waves in reality come in finite packets that involve a whole set of waves with different wave numbers and frequencies. The rate of energy transmission by these wave packets is the group velocity $c_g = \nabla_k \omega$. The group velocity can have various values in various parts of the spectrum. This means that different parts of a wave group propagate generally with different velocities. This process causes the energy to the group to be dispersed over large volumes or areas. The transfer of energy between different

components of a wave spectrum involves nonlinear interactions in eqns [4] and [5].

The waves with the wavelengths λ in the range $\lambda \gg \lambda_\gamma = 2\pi(\gamma/\rho_w g)^{1/2}$ ($\lambda_\gamma \approx 0.0173$ m) are not affected by the surface tension and they are the gravity surface waves with the dispersion relation:

$$\omega^2 = gk \tan h(kH), \quad [7]$$

while the waves with the wavelengths of the range $\lambda_\gamma \gg \lambda$ are the capillary waves, or ripples, with the dispersion relation:

$$\omega^2 = (\gamma k^3 / \rho_w) \tan h(kH). \quad [8]$$

If the depth H is much larger than the wavelength λ , $kH \gg 1$ and $\tan h(kH) \approx 1$, then the dispersion relation [7] reduces to $\omega^2 = gk$ (deep-water waves) and phase velocity magnitude is defined by $c = (g/k)^{1/2} \gg c_{\min} = (4\gamma g / \rho)^{1/4} \approx 0.23 \text{ m s}^{-1}$. The displacements, the particle velocities, and the oscillatory part of the pressure decrease exponentially with increasing depth, with a factor $\exp(2\pi z / \lambda)$. At a depth equal to half a wavelength, the wave motion is reduced to about 1/23 of its surface amplitude.

If the gravity waves are long and the water is relatively shallow, $kH \ll 1$ and $\tan h(kH) \approx kH$, the dispersion relation [7] reduces to $\omega^2 = gk^2 H$ (shallow-water or long waves including tidal waves) and the magnitude of phase velocity is $c = (gH)^{1/2}$. In shallow-water waves, the vertical velocity decreases linearly from the surface to bottom while the horizontal velocity and the pressure perturbation do not change with depth, and barometric pressure relation is satisfied.

Second-Order Waves

The wave steepness parameter $ak = 2\pi a / \lambda$ defines the maximum surface slope associated with a particular harmonic wave. Waves cannot persist if $ak > 1$ or $a/H > 1$ because the local, horizontal water velocity at the wave crest will be larger than the wave phase speed c . The wave must break in this case. Wave steepness can be related also to the ratio of the maximum vertical acceleration to the restoring force. This ratio can be considered as a wave Froude number Fr (ratio of inertial to gravitational acceleration), which, in the case of the deep water gravity waves, is $Fr = \max[(v_3 \partial v_3 / \partial z)_{z=0}] / g = (ak)^2$. Stokes (1847) first established the second-order nonlinear effects for periodic plane gravity wave on deep water. The actual shape of this wave profile is a curve known as a trochoid: the crests are steeper and the troughs are flatter. This feature becomes accentuated as the wave amplitude increases. The dispersion relation includes a second-order correction in the form $\omega^2 = gk(1 + a^2 k^2)$ known as amplitude (or nonlinear) dispersion. The modified phase velocity expression is $c = [(g/k)(1 + a^2 k^2)]^{1/2}$. The investigations of Stokes wave stability finally established that Stokes waves on deep water are unstable. The Stokes waves become unstable, and must break, when a wave develops a sharp crest with an interior angle of 120° . The nonlinear effects also associate with Stokes drift.

Momentum and Energy of Wave Motion

Wind waves are generated by the transmission of momentum and energy from the air to the water. Wave possesses both

potential energy, arising from the displacement of water particles vertically from their undisturbed water level, and kinetic energy due to the orbital velocity of the particles. The wave momentum per unit surface area of any particular wave is

$$M_{kw} = \rho(ca \times ak)/2. \quad [9]$$

The total wave momentum of all wave numbers is

$$M_w = \rho \iint c \Phi(\mathbf{k}) k dk_1 dk_2, \quad k = \sqrt{k_1^2 + k_2^2}, \quad [10]$$

where $\Phi(\mathbf{k}) = \Phi(k, \alpha)$ is the space with polar coordinates (k, α) . The wave energy of any particular constituent wave per unit surface is

$$E_{kw} = c \cdot M_{kw} = \rho(c^2 a \times ak)/2. \quad [11]$$

The specific energy of the complete wave field is obtained by integration of over all wave numbers or frequencies:

$$E_w = \rho g \iint \Phi(k, \alpha) k dk d\alpha = \rho g \int \Psi(\omega) d\omega, \quad [12]$$

and the wave elevation variance is

$$\sigma_\zeta^2 = \overline{\zeta(x, y, t)^2} = \iint \Phi(k, \alpha) k dk d\alpha = \int \Psi(\omega) d\omega, \quad [13]$$

where $\Phi(k)$ and $\Psi(\omega)$ are the spectra in 2D- k -space and ω -space, respectively.

Wave energy budget for a particular wave number $\mathbf{k}$ in the presence of a mean current with velocity $\mathbf{U}$ and energy source/sink S_k is written as

$$\partial E(\mathbf{k}) / \partial t + ((c_g + \mathbf{U}) \cdot \nabla) E(\mathbf{k}) = S_k, \quad E(\mathbf{k}) = \rho g \Phi(\mathbf{k}). \quad [14]$$

The left hand side describes energy propagation through a nonhomogeneous medium (currents, variable depth). The right hand side consists of source terms describing energy input by wind (S_{in}), sinks (whitecapping dissipation S_{ds} and bottom terms), and a nonlinear interaction term S_{sn} . S_{sn} is a very intensive redistributor of energy, momentum, and wave action along the spectrum. Due to S_{sn} , the direct cascades of energy and momentum as well as inverse cascades of wave action are formed. These processes govern the evolution of the wind-wave spectral peak, characterized by the spectral peak phase speed $c = c_0 = [(g/k_0)]^{1/2} = g/\omega_0$, and play a central role in the formation of the universal spectrum behind the spectral peak. Most popular form of these spectra are Phillips spectrum $\Psi(\omega) = \beta_p g^2 \omega^{-5}$, $\beta_p \approx 0.01$; Pierson-Moskovitz's spectrum $\Psi(\omega) = 1.25 \beta_p g^2 \omega^{-5} \exp(-1.25(\omega_0/\omega)^4)$; JONSWAP wave spectrum; and the Kolmogorov-Zakharov wave spectra $\Psi(\omega) \sim \omega^{-4}$, an exact solution of the stationary kinetic equation.

Wave Prediction

The principles of wave prediction were well known at least by 1960s. None of the wave models developed in the 1960s and 1970s computed the wave spectrum from the full energy balance equation. The first models in the 1960s and 1970s assumed that the wave components suddenly stopped growing as soon as they reached a universal saturation level. Here, the saturation spectrum was represented by Phillip's one

dimensional ' ω^{-5} ' frequency spectrum and an empirical equilibrium directional distribution. Today it is generally recognized that a universal high-frequency spectrum (region between 1.5 and 3 times the peak frequency) does not exist because the high-frequency region of the spectrum not only depends on whitecapping but also on winds and on the low-frequency regions of the spectrum through nonlinear transfer. Therefore, the first-generation wave models exhibit basic shortcomings by overestimating the wind input and disregarding nonlinear transfer.

The second-generation wave models attempted to simulate properly the overshoot phenomenon and the dependence of the high-frequency region of the spectrum on the low frequencies. However, the nonlinear transfer parameterization requires the spectral shape of the wind sea spectrum to be prescribed. These models suffered basic problems on the treatment of wind sea and swell.

The wave spectrum was computed by the integration of the energy balance equation [8,13] without any prior restriction on the spectral shape in the third-generation wave models. At present the state of the art in wave models are WAM (a third-generation wave model) and WAVEWATCH, which were developed by international groups and are based on a detailed physical description of air-sea interaction. A prediction of significant wave height requires a prediction of the wave spectrum. Based on specified surface-wind stress (and current) fields at all times, the wave energy balance is solved to obtain the spectra (and the significant wave heights) in wave predictions. However, the fact that today two of the most popular contemporary models, WAM and WAVEWATCH, operational at two of the most prominent meteorological centers, use different approaches to the problem is an indication that a single 'best' solution has not yet been accepted.

Rogue Wave

Freak, rogue, or giant waves correspond to large-amplitude waves surprisingly appearing on the sea surface ('wave from

nowhere') have been a part of marine folklore for centuries. According to the definition of freak waves they are too high, too asymmetric, too steep, and their height exceed the significant wave height by 2–2.2 times. The data of marine observations as well as laboratory experiments demonstrate that freak waves may appear in deep and shallow waters. The probabilistic theoretical approach shows that numerical simulations of freak waves should be made for very long times on large spatial domains and large number of realizations. Theoretical studies show the main features of the physical mechanisms of rogue wave phenomenon. The prediction of rogue wave is based on data analysis with use of statistical methods, but it is not too productive due to the rare character of the rogue waves.

Marine and Oceanic Surface Layers

An important feature of the atmospheric boundary layer over the ocean is the expenditure of momentum and energy of the wind on the generation of waves and currents. This constitutes a fundamental difference of the atmospheric surface layer not only from the ordinary layer above smooth or rough solid surfaces. The thickness of the marine surface layer, **Figure 1**, is of a few tens of meters that heights z above the mean water surface are in the range $H_{E,atm} \gg L_{atm} > z > L_{w-t,atm}$. A distinctive property of this layer is that within it, the vertical fluxes of momentum, heat, moisture, and various types of passive impurities vary little with height and at the horizontal scales much greater than its thickness. These peculiarities allow reducing eqns [1] and [2] to the form of horizontally uniform turbulent boundary layer ('wall turbulence') where these fluxes do not depend on spatial coordinates. The turbulent boundary layer of the atmosphere is stratified; turbulent processes within it are influenced by buoyancy, which in turn results from changes in air density owing to fluctuations in temperature and humidity. The turbulence of the main interval of the atmospheric surface layer at a distance above sea level greater than a few times the height of the largest waves is well described by the Monin-Obukhov (MO) theory. The MO theory establishes

Figure 1 Diagram of dynamic air-sea interaction and dynamical layering of the atmospheric and oceanic boundary layers.

that the turbulent flow is governed by mechanical and thermal forcing, and the statistical characteristics of turbulence are determined by the height above the surface, z , the buoyancy parameter, $\beta = g/S^0$, the friction velocity, u_{*r} , and the vertical turbulent heat flux $Q_T = \rho_{a0} c_{pa} \overline{T' u'_3}$ (T' , u'_3 are turbulent fluctuations of air/seawater temperature and vertical velocity; $u_* = u_{*a}$ in the atmosphere or $u_* = u_{*w}$ in the ocean; S^0 is either air reference potential temperature θ_{a0} or seawater reference density ρ_{w0} ; c_p is the specific heat of air at constant pressure $c_{pa} = 1004 \text{ J K}^{-1} \text{ kg}^{-1}$ or seawater $c_{pw} = 4218 \text{ J K}^{-1} \text{ kg}^{-1}$). Conclusions derived from the MO theory are the principal tool for calculating the characteristics of the turbulent atmospheric surface layer. The atmospheric MO-length scale,

$$L_{MO} = -\rho_{a0} c_{pa} u_{*a}^3 / \kappa \beta Q_T, \quad [15]$$

characterizes buoyancy influence in the MO-turbulent boundary layer (Figure 1), $\kappa = 0.4$ is the Karman constant. The sign of the MO-similarity variable $\zeta = z/L_{MO}$ indicates that the stratification of the turbulent boundary layer is stable if $\zeta > 0$, or unstable if $\zeta < 0$ (the z -axis is positive in upward direction in the atmosphere, Figure 1). The buoyancy influence on turbulence is most significant when $|\zeta| \gg 1$ (thermal convection if $\zeta < 0$, or strong stable stratification if $\zeta > 0$; in thermal convection case, the friction velocity does not contribute into turbulent statistical characteristics except the vertical profile of mean wind). The buoyancy does not affect the turbulence if $|\zeta| \ll 1$, and then the turbulence is similar to the 'wall turbulence' in a fluid with constant density (neutral stratification) or the 'logarithmic' turbulent boundary layer. Thus the mean vertical profiles of wind speed, air temperature, and humidity well follow to their theoretical logarithmic form which depends on an additional parameter z_0 , the roughness parameter of underlying surface or the roughness length scale of underlying surface, and, in our case, is $z_0 \ll L_{w-t,atm}$. The formal definition z_0 states that z_0 is the height above the mean underlying surface at which the mean wind velocity, defined by the 'logarithmic' law, is zero. A characteristic of an actual immobile surface is the mean height h_0 of the actual protrusions on it, and z_0 is in a proportion to h_0 . The underlying surface is dynamically smooth if h_0 is small as $h_0 < 36z_v$, or it is dynamically completely rough if $h_0 > 540z_v$ ($z_v = \nu_a/9 u_{*a}$ is the viscous friction length scale of the dynamically smooth surface, $z_0 = z_v$), and, hence, z_0 of any immobile surface characterizes h_0 if $z_0 \geq z_v$. The sea surface roughness z_0 , in difference to immovable surfaces, varies in a very wide range ($10^{-7} \text{ m} < z_0 < 0.1 \text{ m}$), and in some situations is even less than z_v ($z_0 < z_v$). Field observations and theoretical studies established that z_0 predominantly depends on the surface wave age $\varsigma = c_0/u_{*a} = [(g/u_{*a}^2 k_0)]^{1/2} = g/u_{*a} \omega_0$. The field measurements at height 10 m presented in the form $\ln(z_0/z_v)$ versus the wave age $\varsigma = c_0/u_{*a}$ can be approximated as

$$\begin{aligned} 11.5 \geq \ln(z_0/z_v) &= 14 - 0.516\varsigma + 2.74 \times 10^{-3}\varsigma^2 \\ &\geq -10.25, \quad 5 \leq \varsigma \leq 90, \end{aligned} \quad [16]$$

where $z_0 = z_v$ at $\varsigma = \varsigma_* = 32.87$. This empirical formula allows dividing the range of ς onto two main regions: the region of developing waves $5 \leq \varsigma \leq \varsigma_*$, which corresponds to the rough sea surface $z_0 \geq z_v$, and the region $\varsigma_* \leq \varsigma \leq 90$, which corresponds to the 'oversmoothed' sea surface $z_0 \leq z_v$ when the wind

is weak and a swell propagates in the same direction or in a situation of slackening wind but with already developed waves. The wind waves are the developed waves when $\varsigma \approx \varsigma_*$. This classification is common in physical oceanography. In the case of developing waves ($5 \leq \varsigma \leq \varsigma_*$), the wind transfers its momentum and energy to waves, the sea surface is rougher for young waves (small values ς) and becomes, in aerodynamic sense, 'smooth' ($z_0 \approx z_v$) for mature, or developed, waves when $\varsigma \rightarrow \varsigma_*$. In the case of the 'oversmoothed' sea surface ($z_0 \leq z_v$), the waves momentum and energy transfer to the wind. Hence, in difference to the roughness of hard immovable surfaces, the sea surface roughness has the dynamical nature.

Charnock's formula (Elison, 1956; Charnock, 1955) $z_0 = m u_{*a}^2/g$, where m is the Charnock's constant, is a well-known expression for calculating z_0 of sea surface. Numerous estimates of the numerical value of m from field measurements and laboratory experiments point out that m varies in the broad range as $10^{-3} < m < 1$ (data by Donelan et al., 1993). It is not a universal constant but a function of the wave age ς in the case of developing waves ($5 \leq \varsigma \leq \varsigma_*$). The function $m \approx 355\varsigma^{-3.64}$ roughly approximates the data of this range of ς .

In the layer of air between the logarithmic sublayer and the water surface – the airwave-turbulent sublayer in Figure 1, the theory of similarity cannot be applied because the disturbances, induced by waves, cause strong influence on the dynamics of this layer. The effect of this factor shows up in all characteristics of turbulence and is still poorly understood. The effective mechanism is redistribution of the vertically invariant flux of momentum between the turbulent and wave components of momentum. In this sublayer, about 10 m thick, waves make a significant contribution to the mean and fluctuating fields. The mean velocity profile deviates from logarithmic law, these deviations are positive or negative depending on the wave age with maximum of measured values of about $\pm 0.5 \text{ m s}^{-1}$ at the heights (accessible for measurements) closest to the sea surface (+ for developing waves ($\varsigma - \varsigma_* < 0$), – for waves with $\varsigma - \varsigma_* > 0$). The waves increase the intensity of the fluctuations and change the nature of the correlation between the fluctuation characteristics. The peaks produced by waves are clearly distinguishable in the fluctuation spectra. The waves also make a considerable contribution to the total fluxes of momentum, heat, and moisture. The mathematical procedure for filtering stationary random processes can be used to reconstruct the contributions of waves and turbulence.

Air–Sea Fluxes and Surface Waves

Momentum, Energy Fluxes, and Breaking Waves

As it was noted above, the surface atmospheric boundary layer is the boundary layer with the constant vertical fluxes of momentum, energy, heat, and humidity over its entire thickness including the wave-turbulence sublayer (Figure 1). Therefore, the vertical fluxes in the logarithmic sublayer can be accepted as the actual fluxes and all mean characteristics of the boundary layer should be taken at the height $z_a = 10 \text{ m}$ as the standard reference height where the wave disturbances are negligibly small.

The turbulent fluxes of momentum ($\tau_{1,3} = -\rho_{a0} \overline{u'_1 u'_3} = \rho_{a0} u_*^2$), sensible heat ($Q_T = \rho_{a0} c_{pa} \overline{T' u'_3}$), and humidity

($Q_E = \rho_{a0} \overline{q' u_3'}$, q' is the specific humidity fluctuation) have traditionally been estimated by using bulk form:

$$\begin{aligned} \tau_{1,3}/\rho_{a0} &= u_*^2 = C_u U_{10}^2, Q_T/\rho_{a0} c_{pa} \\ &= -C_T U_{10} (T_{a,10} - T_{ws}), p_{a0} Q_E/\rho_{a0} \\ &= -C_E U_{10} (E_{10} - E_{ws}), \end{aligned} \quad [17]$$

where C_u is the drag coefficient of sea surface, C_T is the heat transfer coefficient, and C_E is the evaporation coefficient; U_{10} , $T_{a,10}$, E_{10} are the mean values of wind speed, air temperature in °C and humidity at the height $z_a = 10$ m; T_{ws} is the water surface temperature in °C; here the specific humidity $q \approx 0.622 \times E/p_{a0}$, where E is the partial pressure of water vapor and the atmospheric pressure on the Earth's surface p_{a0} in hPa, $p_{a0} = 1013$ hPa; E_{ws} is the humidity of saturated vapor at water surface temperature T_{ws} and can be found with the help of the known expression:

$$E_{ws} = 6.1 \exp(7.45 T_{ws} (235 + T_{ws})^{-1}). \quad [18]$$

The latent heat fluxes Q_E can be found using the formula:

$$Q_E = -\rho_a A_e p_{a0}^{-1} \times 0.622 \times C_E \times U_{10} (E_{10} - E_{ws}), \quad [19]$$

where $A_e = 2.45 \times 10^6$ J kg⁻¹ is the specific latent heat of evaporation.

The variability of the coefficients C_u , C_T , C_E constitutes one and half orders of magnitude; measurement data place their values in the range $0.5 < (C_u, C_T, C_E) \times 10^3 < 10$. In the case of developing waves ($\zeta - \zeta_* < 0$) and wind conditions $U_{10} > 3$ m s⁻¹, the drag coefficient C_u is a decreasing function of the wave age ζ . The empirical data and theoretical calculations – mutual wind-wave adaptation model – well follow to the approximation $C_u(\zeta) \approx 0.5[1 + 1.3 \times \tan h(\zeta/\zeta_*)] \zeta^{-2}$ for the wave age range of $10 < \zeta \leq \zeta_*$. Examples of C_u variations versus the wind speed U_{10} – one of traditional forms of description the drag coefficient variability – are shown in Figure 2 where numerical modeling results are shown along with observation data.

The variabilities of the heat transfer coefficient C_T and the evaporation coefficient C_E are very similar to the variability of

Figure 2 Dependence of model drag coefficients at $z = 10$ m and $\zeta = 10, 20, 30$. Three other curves with 'very young,' 'mature,' and 'full' from observed data by Ly and Garwood (2000).

the drag coefficient C_u . The dependence C_T versus C_u is given by the empirical expression

$$C_T(\zeta) \approx A_1 [1 - 17 \sqrt{C_u(\zeta)}] C_u(\zeta) \quad [20]$$

with the constant $A_1 \sim 1$. This formula agrees well with the conclusions from the theoretical analysis of the transformation of thermal regime of the surface atmospheric layer in the presence of wind-wave interaction. It is recommended in a literature that the averaged values of $C_T \approx C_E$.

In the case of developing waves, the characteristics of the wave field c_0 and σ_ζ can be found as functions of the wave age ζ using the approximation for the drag coefficient C_u and the Phillips spectrum ' ω^{-5} .' These estimates are

$$\begin{aligned} \frac{c_0}{U_{10}} &\approx \sqrt{0.5 \times [1 + 1.3 \times \tan h(\zeta/\zeta_*)]}, \quad \frac{g\sigma_\zeta}{U_{10}^2} \approx 0.5 \beta_p^{1/2} \zeta^2 C_u \\ &\approx \frac{\beta_p^{1/2}}{4} [1 + 1.3 \times \tan h(\zeta/\zeta_*)]. \end{aligned} \quad [21]$$

$$10 < \zeta \leq \zeta_*$$

They fit to the observations and the theory of mutual wind-wave adaptation. If the wave field can be considered as the developed wave field, i.e., $\zeta \approx \zeta_*$, then for $\zeta_* = 32.87$,

$$C_u(\zeta_*) \approx 0.92 \times 10^{-3}, \quad \frac{c_0(\zeta_*)}{U_{10}} \approx 1, \quad \frac{g\sigma_\zeta}{U_{10}^2} \approx 5 \times 10^{-2}. \quad [22]$$

In the case of very weak wind condition or nearly calm weather, when $U_{10} < 3$ m s⁻¹, the estimates of sensible and latent heat fluxes by standard meteorological measurements can be found by formulas:

$$Q_T = -\frac{0.14 \rho_a c_{pa}}{\text{Pr}_T^{1/3}} \Delta T \left[\left(\frac{\Delta T}{T} + 0.61 \times \left(0.622 \times \frac{\Delta E}{p_{a0}} \right) \right) g D_T \right]^{1/3}, \quad [23]$$

$$\begin{aligned} Q_E &= -\frac{0.14 \rho_a A_e}{\text{Pr}_E^{1/3}} \times \left(0.622 \frac{\Delta E}{p_{a0}} \right) \\ &\times \left[\left(\frac{\Delta T}{T} + 0.61 \times \left(0.622 \times \frac{\Delta E}{p_{a0}} \right) \right) g D_E \right]^{1/3}, \end{aligned} \quad [24]$$

where $T = 273 + T_{a,10}$ is the reference temperature of air at measurement height $z_a = 10$ m where $T_{a,10}$ in °C, $\text{Pr}_T = \nu_a/D_T = 0.72$ and $\text{Pr}_E = \nu_a/D_E = 0.6$ are the Prandtl numbers, D_T is the thermal molecular diffusivity, D_E is the molecular diffusivity for water vapor, $\Delta T = T_{a,10} - T_{ws}$, $\Delta E = E_{10} - E_{ws}$.

Spray

The presence of spray in the atmospheric surface layer influences dynamic and thermodynamic processes in the surface layer. Wind gives rise to sea spray through various mechanisms, but bubble bursting is the primary one. Increasing wind speed causes a corresponding increase in the production of white caps at the ocean surface. These white caps form bubbles in the ocean which, when breaking at the surface, produce sea spray. The sea spray can be observed at heights of more than 10 m above the ocean surface in the atmospheric surface layer. The wave motion and turbulent mixing act as lifting forces on the

sea spray. Because of the difference in the motions of small and large droplets, the particle size distribution changes with height, with relatively more small droplets in the upper layers. Some theoretical calculations indicate an increase in the drag of the surface and the rate of evaporation. The water drops are also a cause of scattering and absorption of the radiation.

Wave Breaking and the Ocean Upper Layer Turbulence

The velocity field $u(x, t) = (v(x, t) + w(x, t))$, of the upper ocean constitutes of two components: the turbulent component $w(x, t)$, ($\omega(x, t) = \text{curl}u(x, t) = \text{curl}w(x, t)$) and the wave component $v(x, t)$, ($v(x, t) = \nabla\varphi(x, t)$). The mean currents, or the mean velocity $u(x, t)$, is mostly associated with the turbulent component $w(x, t)$, i.e., $\overline{u(x, t)} = \overline{w(x, t)}$ is the wind-driven current with the surface drift speed U_s . The potential wave field, in a sense of accumulated kinetic energy, is a leading member of the energy contributors in the upper part of the Ekman layer (Figure 1, the depth $z > 0$ is downward). In terms of characteristic scales of velocities, they are allocated in the order $|v(x, t)| > U_s \geq |\overline{u(x, t)}| > |\overline{w'(x, t)}|$. The speed of surface drift has simple empirical estimate as $U_s \approx k_d U_{10}$ with the surface drift coefficient $k_d \approx 1/30$. The estimate of the kinetic energy of the wave motions $k_v = \overline{v \cdot v}/2$ over the entire thickness of the constant friction layer, assuming the horizontal uniformity of the wave field and using the linear theory of waves, is

$$k_v = 0.5\beta_P c_0^2 \left(1 + \sqrt{z/L_{*v}}\right) \exp\left(-\sqrt{z/L_{*v}}\right), \quad L_{*v} = c_0^2/24g \\ = \sigma_\zeta/12\sqrt{\beta_P}. \quad [25]$$

In the case of developing waves when $10 \leq \zeta \leq \zeta_*$, the wave kinetic energy in eqn [25] yield to a function of the depth z and the wave age ζ in the form:

$$k_v(z, \zeta) = U_{10}^2 \frac{\beta_P}{4} \left[1 + 1.3 \times \tan h\left(\frac{\zeta}{\zeta_*}\right)\right] \times \left[1 + \sqrt{\frac{12z\sqrt{\beta_P}}{\sigma_\zeta(\zeta)}}\right] \\ \times \exp\left[-\sqrt{\frac{12z\sqrt{\beta_P}}{\sigma_\zeta(\zeta)}}\right]. \quad [26]$$

The wave kinetic energy increases with $\zeta \rightarrow \zeta_*$; however, $k_v(z, \zeta)$ at the wave age of the range $10 \leq \zeta \leq \zeta_*$ always satisfies to the inequality:

$$k_v(z, \zeta) \leq k_v(z, \zeta_*) \\ = U_{10}^2 \beta_P \times \left(0.5 + \sqrt{\frac{6gz}{U_{10}^2}}\right) \times \exp\left(-2\sqrt{\frac{6gz}{U_{10}^2}}\right). \quad [27]$$

The turbulent energy production by the wave breaking exceeds significantly the mean shear effect in the vicinity of the ocean surface. The general dynamic structure of the turbulent upper layer is produced by wave breaking and turbulent diffusion of the wave kinetic energy. According to the Longuet-Higgins' parameterization, the waves lose simultaneously some part of the obtained momentum and energy because the wave

breaking produces the momentum and energy fluxes τ_{wb} and q_{wb} . These fluxes, or the rate of the wave momentum M_w and energy E_w decay per the characteristic wave cycle ω_0 , can be expressed for the wave age $\zeta \leq \zeta_*$ as

$$\tau_{wb} = \gamma_1 \omega_0 M_w = \frac{\gamma_1 \beta}{3} \rho_w c_0^2, \quad q_{wb} = \gamma_2 \omega_0 E_w = \frac{\gamma_1 \beta}{3} \rho_w c_0^3, \quad [28]$$

where $\gamma_1(\zeta) \leq \gamma_1(\zeta_*) \approx 3 \times 10^{-4}$, $\gamma_2 = (4/3) \times \gamma_1$ are the dimensionless constants representing the fractions of the wave momentum and energy spent in the wave breaking.

The model equations (k - ε group model) take into account the presence of potential surface waves. In this model, $k_T = \overline{w'w'}/2$ is the turbulent kinetic energy, $\nu_T = c_v \varepsilon^{-1} k_T^2 = \ell k_T^{1/2}$ is the traditional form of the turbulent viscosity, where ε is the dissipation rate, ℓ is the length scale of turbulent mixing, and $c_v = 0.09$ is the Kolmogorov's closure constant. The turbulent kinetic energy budget contains an extraterm, $0.5 \overline{w'_3 w'}$, which is the turbulent flux of the wave kinetic energy.

Wave-Turbulent Sublayer

The wave-turbulent sublayer (Figure 1) is a layer where the turbulent flux of the wave kinetic energy, $0.5 \times \overline{w'_3 w'}$, causes dominative influence in the dynamic of this layer. The given definition can be presented in the formal form:

$$|\partial_z k_T| \ll \sigma |\partial_z k_v|, \quad \nu_T (\partial_z \overline{U})^2 \ll \varepsilon, \quad 0 \leq z \leq L_{w-v}, \quad [29]$$

where $\sigma \approx 0.03$ is the closure constant in the diffusive approximation of the turbulent flux of the wave kinetic energy, and $0.5 \times \overline{w'_3 w'}$, $\overline{U}$ is the velocity of the mean current, $L_{w-v} \approx 5.1 \times L_{*v}$ is the thickness of the wave-turbulent sublayer. The principal statistical characteristics of turbulence in the wave-turbulence sublayer are given by the following equations:

$$k_T = k_T(0) \frac{3 \left(1 + \sqrt{z/L_{*v}}\right) \exp\left(-\sqrt{z/L_{*v}}\right)}{2 + \left(1 + \sqrt{z/L_{*v}}\right)^3 \exp\left(-3\sqrt{z/L_{*v}}\right)}, \quad [30]$$

$$k_T(0) \approx 1.3(\gamma_1 \beta_P)^{2/3} c_0^2 = 2.7 \times 10^{-4} c_0^2,$$

$$\varepsilon = \varepsilon(0) \frac{3^{3/2} \left(1 + \sqrt{z/L_{*v}}\right)^{1/2} \exp\left(-\frac{3}{2}\sqrt{z/L_{*v}}\right)}{\left[2 + \left(1 + \sqrt{z/L_{*v}}\right)^3 \exp\left(-3\sqrt{z/L_{*v}}\right)\right]^{3/2}},$$

$$\varepsilon(0) \approx 4\gamma_1 \beta g c_0 = 1.2 \times 10^{-5} g c_0,$$

$$\ell = \ell(0) \left(1 + \sqrt{z/L_{*v}}\right), \quad \ell(0) = \sigma_\zeta/15\sqrt{\beta_P} = c_0^2/30g, \quad [32]$$

$$\nu_T = \nu_T(0) \frac{3^{1/2} \left(1 + \sqrt{z/L_{*v}}\right)^{3/2} \exp\left(-\frac{1}{2}\sqrt{z/L_{*v}}\right)}{\left[2 + \left(1 + \sqrt{z/L_{*v}}\right)^3 \exp\left(-3\sqrt{z/L_{*v}}\right)\right]^{1/2}},$$

$$\nu_T(0) = 0.038(\gamma_1 \beta_P)^{1/3} \frac{c_0^3}{g}. \quad [33]$$

The dissipation rate in the form of eqn [31] is well supported by the field measurements.

Diffusive Turbulent Sublayer

The diffusive turbulent sublayer is a transition zone between the wave-turbulent subsurface layer and the layer where the mean shear flow controls the turbulent regime. The depths of its location are in the range $L_{W-v} \leq z \leq L_W$, where L_W is the lower boundary of the transitional diffusive sublayer. In this region the turbulent diffusion still exceeds the mean shear contribution in the turbulent kinetic energy budget but the wave motion effect becomes insignificant, or in a formal form as

$$|\partial_z k_T| \ll \sigma |\partial_z k_V|, \quad \nu_T (\partial_z \bar{U})^2 \ll \varepsilon, \quad L_{W-v} \leq z \leq L_W, \quad [34]$$

where L_W is the lower boundary of the transitional diffusive sublayer. Taking the coordinate z as $z = L_{W-v} + z_1$, the principal turbulent characteristics of the diffusive turbulent sublayer can be found as a solution of the equations in the $k - \varepsilon$ -turbulence form:

$$\begin{aligned} 0 \leq z_1 \leq L_W - L_{W-v}, \quad k_{T1} &= \frac{k_{T1}(0)}{(1 + z_1/L_{*1})^{n_k}}, \quad \varepsilon_1 \\ &= \frac{\varepsilon_1(0)}{(1 + z_1/L_{*1})^{n_\varepsilon}}, \quad \nu_{T1} = \frac{\nu_{T1}(0)}{(1 + z_1/L_{*1})^{n_{VT}}}, \quad \ell \\ &= \ell(0)(1 + z_1/L_{*1}), \end{aligned} \quad [35]$$

$$n_k = \frac{4}{\mu - 7}, \quad n_\varepsilon = \frac{\mu - 1}{\mu - 7}, \quad n_{VT} = \frac{9 - \mu}{\mu - 7}, \quad [36]$$

$$7 < \mu = \sqrt{1 + 24c_2 \text{Pr}_\varepsilon / \text{Pr}_k} \leq 9, \quad 2 < c_2 \text{Pr}_\varepsilon / \text{Pr}_k \leq \frac{10}{3}, \quad [37]$$

$$\begin{aligned} k_{T1}(0) &= [q_{W-v}(L_{W-v})\varepsilon(L_{W-v})L_{*1}\text{Pr}_k(\mu - 7)/4c_v]^{1/3}, \quad \varepsilon_1(0) \\ &= \varepsilon(L_{W-v}), \end{aligned} \quad [38]$$

$$\begin{aligned} \nu_{T1}(0) &= \frac{c_v k_{T1}(0)^2}{\varepsilon(L_{W-v})\text{Pr}_k}, \quad \ell(0) = \frac{c_v k_{T1}(0)^{3/2}}{\varepsilon(L_{W-v})}, \quad L_{*1} \\ &= \frac{6q_{W-v}(L_{W-v})}{(\mu - 7)\varepsilon(L_{W-v})}, \end{aligned} \quad [39]$$

where c_2 , Pr_ε , Pr_k are the closure constants in the $k - \varepsilon$ -turbulence with the recommended numerical values $c_2 \approx 1.92$, $\text{Pr}_\varepsilon \approx 1.3$, $\text{Pr}_k \approx 1$. Pr_k and Pr_ε are the turbulent Prandtl numbers for the turbulent kinetic energy and the dissipation rate consequently. However, observation data support for the dissipation rate decay the law ' $\varepsilon \sim z^{-4}$ '. Then $n_k = 2$, $n_\varepsilon = 4$, $n_{VT} = 0$, and the turbulent viscosity $\nu_{T1} = \nu_{T1}(0) = \text{const}$ in the turbulent diffusive sublayer. Also, because the values $c_2 = 1.92$ and $\text{Pr}_k = 1$ are most popular their numerical estimates, the Prandtl number for the dissipation rate is $\text{Pr}_\varepsilon = 10\text{Pr}_k/3c_2 \approx 1.736$ instead of the recommended $\text{Pr}_\varepsilon \approx 1.3$. The 'wall turbulence' sublayer provides an additional equation to find Pr_k and Pr_ε , which are consistent with the turbulent diffusive sublayer law ' $\varepsilon \sim z^{-4}$ ' and the 'wall turbulence' sublayer.

'Wall Turbulence' Sublayer

Following after the turbulent diffusive sublayer, there is a layer, located at the depths z in the range $L_W \leq z \leq L$ (Figure 1, L is the lower border of the constant friction layer), where the mean

shear production of turbulent energy dominates. The formal conditions for the layer existence in the steady case take a form:

$$|\text{Pr}_k^{-1} d_{z_2} \nu_{T2} d_{z_2} (k_{T2} + \sigma k_V)| < \nu_{T2} (d_{z_2} \bar{U})^2, \quad 0 \leq z_2 \leq L - L_W \quad [40]$$

where the coordinate z is $z = L_W + z_2$. The principal turbulent characteristics of the 'wall turbulence' sublayer can be found at the depth $0 \leq z_2 \leq L_W - L_{W-v}$ as a solution of the equations in the $k - \varepsilon$ -turbulence form:

$$\begin{aligned} \bar{U}(L_W) - \bar{U}(z_2) &= \frac{u_{*W}}{\kappa} \ln \left(\frac{z_2 + L_{*2}}{L_{*2}} \right), \quad k_{T2} = \frac{u_{*W}^2}{\sqrt{c_v}} \\ &= \text{const}, \quad \varepsilon = \frac{\varepsilon_1(L_W)L_{*2}}{z_2 + L_{*2}}, \end{aligned} \quad [41]$$

$$\nu_{T2} = \kappa(L_{*2} + z_2)u_{*W}, \quad \ell = \kappa \sqrt{c_v}(L_{*2} + z_2), \quad [42]$$

$$L < L_{*2} [\exp(\kappa \bar{U}(L_W)/u_{*W}) - 1], \quad L_{*2} = u_{*W}^3 / \kappa \varepsilon(L_W), \quad [43]$$

$$\kappa = \sqrt{\text{Pr}_\varepsilon \sqrt{c_v}(c_2 - c_1)}. \quad [44]$$

The numerical values for constants c_v , c_1 , c_2 , and Pr_ε , given in textbooks as the most popular estimates ($c_v = 0.09$, $c_1 = 1.44$, $c_2 = 1.92$, $\text{Pr}_k = 1$, $\text{Pr}_\varepsilon = 1.3$), give the Karman constant $\kappa \approx 0.433$ instead of the classical numerical value $\kappa \approx 0.4$. If the closure constants $c_v = 0.09$, $c_1 = 1.44$, $c_2 = 1.92$, and $\kappa = 0.4$ represent their better established numerical values then the law ' z^{-4} ' of the dissipation decay in the diffusive sublayer with eqn [44] of the 'wall turbulence' sublayer define the turbulent Prandtl numbers Pr_k and Pr_ε as

$$\text{Pr}_k = \frac{3c_2 \kappa^2}{10 \sqrt{c_v}(c_2 - c_1)} \approx 0.64, \quad \text{Pr}_\varepsilon = \frac{\kappa^2}{\sqrt{c_v}(c_2 - c_1)} \approx \frac{10}{9}, \quad [45]$$

which are consistent to both sublayers.

Bubbles

Breaking waves at the ocean's surface inject bubbles into the water column. Gas bubbles near the surface of the ocean are important in underwater sound propagation, meteorology, sea surface chemistry, and air-sea gas exchange. Depending on their concentrations and size distribution, the entrained bubbles can significantly change the optical properties of water. Once air is entrapped at the sea surface, there is a rapid development stage resulting in a cloud of bubbles. Some bubbles will be several millimeters in diameter, but the majority will be less than 0.1 mm in size. Each bubble is buoyant and will tend to rise toward the sea surface, but the upper ocean is highly turbulent and bubbles may be dispersed to depths of several meters. Small particles and dissolved organic compounds very often collect on the surface of a bubble while it is submerged. Gas will also be slowly exchanged across the surface of bubbles, resulting in a continual evolution of the size and composition of each bubble. The additional pressure at depth in the ocean will compress bubbles and will tend to force the enclosed gases into solution. Some bubbles will be forced entirely into solution, but generally the majority of the bubbles will

eventually surface carrying their coating and altered contents. At the surface, a bubble will burst, generating droplets that form most of the sea salt aerosol suspended in the lower marine atmosphere.

Introduction

Human society is becoming increasingly dependent on aircraft for long-distance travel and shipping. Among transportation modes, aviation is the fastest-growing; the current passenger growth rate is approximately 4% per year and the average growth rate since 1960 has been nearly 9% per year. The fraction of transport fuel use by aviation has risen steadily to about 13% currently. Because of the robust growth rate, concern has been expressed over possible environmental impacts of future aircraft operation. Vigorous science and technology programs have been pursued over the last decade to define potential atmospheric impacts and identify technological strategies to reduce specific exhaust emissions. Environmental compatibility issues have also been central to efforts to develop future aircraft technologies such as high-speed (i.e., supersonic) civil transport.

Jet aircraft burning hydrocarbon-based fossil fuels transport the bulk of air passengers and freight. Currently there are over 15 000 aircraft serving nearly 10 000 airports worldwide and burning nearly 140 Tg of fuel per year. By the year 2015, fuel burn by aviation is forecast to increase to approximately 300 Tg per year. As with other fossil fuel transportation technologies, jet aircraft operation results in gaseous and particle combustion byproducts. Aircraft engines emit principally carbon dioxide (CO_2) and water (H_2O) with minor contributions from nitrogen oxides (NO_x), sulfur oxides (SO_x), unburned hydrocarbons (HC), and soot. All of these exhaust species are atmospheric pollutants. CO_2 and H_2O are greenhouse gases that affect the Earth's climate directly. NO_x and HC are reactive gases that affect atmospheric ozone and methane levels. Soot, SO_x , HC, and H_2O are aerosol and cloud precursors that affect ozone and climate.

A major difference between aviation and other transportation modes is in the atmospheric placement of the combustion exhaust products. Unlike autos and trucks, by far the greater part (>85%) of aircraft exhaust is released above the planetary boundary layer (>2 km) and a large fraction (~70%) of it is released in the upper troposphere (UT) and lower stratosphere (LS) between 9 and 13 km. Consequently, the major polluting effects of aircraft are expected to occur in the UT/LS region of the atmosphere.

The dynamics of the UT/LS region differ from those of the boundary layer in that there is less vertical mixing and less diurnal variation in wind direction. Because of these differences, pollutants emitted into the UT/LS reside there longer and can spread over considerable longitudinal and, in some cases, latitudinal distances. Although aircraft exhaust is released in geographically narrow flight routes and corridors, its injection into the UT/LS means that the polluting effects of aircraft will be felt on regional and, perhaps, global scales. The longer residence times also enable some pollutants, such as NO_x , to spend extended times cycling through catalytic chemical reaction sets that create or destroy ozone. Because of such enhanced catalytic chemical cycling in the UT/LS, the impact of a given amount of aircraft emissions on atmospheric ozone and climate may be much greater than the same amount of emissions from ground transportation sources.

There are also important dynamical and chemical differences between the UT and LS regions that complicate any analysis of aircraft effects. For example, the lifetime of ozone and the chemical mechanisms controlling its concentration are sensitive functions of altitude in the vicinity of the tropopause. Because of this altitude dependence, the sign of the ozone response to injections of NO_x shifts from positive (net ozone formation) to negative (net ozone destruction)

at altitudes slightly above the tropopause (i.e., the transition between the stratosphere and troposphere). The partitioning of aircraft exhaust between the UT and LS is difficult to define (estimates differ by factors of two) because of the high variability and latitudinal dependence of the tropopause height.

Aircraft Exhaust Products

Jet engines on modern aircraft are composed of three essential elements: compressors that increase the pressure and temperature of the entering air, combustors that mix and burn fuel with incoming air, and turbines that convert the hot gas energy, through compressor activity, to bypass airflow that propels the aircraft. The fuel-to-air ratio in modern combustors is approximately 1:9, hence large quantities of ambient air are processed in aircraft engines. Jet fuel is composed predominately of high-weight (C_{12} – C_{15}) alkanes, with substantially smaller quantities of alkenes and aromatics present. An important trace species in the fuel is sulfur, which can represent up to 0.3% (by weight) of the fuel content.

Combustion of the fuel hydrocarbons to produce CO_2 and H_2O is nearly complete (>99.5%) in commercial aircraft engines. In addition, the fuel sulfur is converted to sulfur dioxide and sulfuric acid, although the precise mechanism for this process remains uncertain. The small fraction of incompletely combusted fuel hydrocarbons give rise to CO and various smaller gaseous hydrocarbons (HC) such as ethene, ethine, and formaldehyde. Under fuel-rich combustor conditions, breakdown of the fuel hydrocarbons leads to formation of soot particulates composed primarily of carbonaceous material. The rate-limiting process in soot formation appears to involve the oxidation of C_2 species such as acetylene (C_2H_2). Decomposition of ambient nitrogen and oxygen also occurs in the high-temperature portions of the combustor, giving rise to the important atmospheric pollutants nitric oxide (NO) and nitrogen dioxide (NO_2) (i.e., NO_x) (Table 1).

Aircraft Technology Considerations

Aircraft engine and airframe technologies have undergone dramatic improvements over the last 30 years. One result of these improvements has been a 70% reduction in fuel burned per passenger seat from early to current jets. Gains in fuel efficiency are of benefit both economically and in environmental terms by reducing fuel costs and uniformly lowering CO_2 , H_2O ,

and SO_x emissions. These gains have derived primarily from increasing gas temperatures and pressures inside the engines. Without concomitant changes in engine design, increasing engine temperature leads to increasing NO_x emissions.

Concern over urban pollution has led to increasingly stringent standards being adopted by the International Civil Aviation Organization (ICAO) regarding emissions of smoke, CO, HC, and NO_x . Aircraft smoke refers to visible particulates in the aircraft plume and presumably includes the large diameter (>1 μm) part of the soot population. The ICAO standards have both reflected and motivated improvements in engine design and manufacture. However, because the service lifetime of an individual aircraft is between 25 and 40 years, the current fleet consists of a combination of older and newer technologies.

Measurement of aircraft cruise emissions is an important facet of assessing impacts and documenting technological advances. These difficult measurements are made either in altitude simulation test cells or by in-flight measurements utilizing target and chase aircraft.

Aircraft Operational Considerations

Airline traffic patterns are highly inhomogeneous, with the bulk of current traffic located inside well-defined ‘flight corridors’ in the Northern Hemisphere (Figure 1). The chemical lifetimes of aircraft exhaust products such as NO_x , soot, and sulfate injected in the UT/LS are comparable to atmospheric mixing times. Consequently, a number of the aircraft chemical perturbations are expected to be localized in regions around the flight corridors. A great deal of work has been done to compile accurate inventories of aircraft emissions. These efforts have involved development of aircraft movement databases based on simplifying assumptions about the airframe–engine combinations used and the paths flown between various city pairs. Combining these movement databases with information on individual aircraft emission rates enables construction of global emissions inventories. For atmospheric modeling purposes, the aircraft emission databases are divided into spatial bins that are 1° longitude $\times$ 1° latitude $\times$ 1 km altitude.

Impacts on Carbon Dioxide and Water

Although they are the most prevalent exhaust products, emissions of CO_2 and H_2O from aircraft represent relatively small sources of these species compared with the many other large natural and anthropogenic sources. Given past and current emission rates, aircraft are responsible for increasing atmospheric CO_2 levels by approximately 1 ppmv or 2% over the last 50 years. Because CO_2 is very long-lived in the atmosphere and is well mixed, it is impossible to distinguish the CO_2 emitted from aircraft from any other source. Perturbations due to aircraft H_2O emissions are far less than 1% globally. These small perturbations are impossible to detect on the large scale because water vapor has a short (days to weeks) tropospheric residence time and its ambient concentrations are highly variable. At very small spatial scales, H_2O perturbations from aircraft are substantial and can lead to contrail and cirrus cloud

Table 1 Approximate emission index levels for cruise level operation of current commercial jet aircraft

Species	Emission index ($g\ kg^{-1}$)
CO_2	3160
H_2O	1240
CO	2
HC	1
NO_x (as NO_2)	12
SO_x (as SO_2)	0.8
Soot	0.04

Figure 1 Calculated NO_x emissions for all aircraft traffic in May 1992 as a function of altitude and latitude, summed over longitude (a), and as a function of latitude and longitude summed over altitude (b). Values greater than the range maximum are plotted as black. (From NASA reference publication 1400.)

formation. These effects have important climate consequences that will be discussed below.

Impacts on Ozone and Methane

Ozone chemistry throughout the stratosphere and troposphere is driven by solar-initiated free radical reactions. Aircraft emit a number of species (i.e., NO_x , SO_x , H_2O , CO, and soot) that participate in ozone-controlling reactions of free radicals and free radical precursors. The relationship between aircraft exhaust products and ozone is complex and depends on the balance between a number of ozone-forming and -depleting chemical processes. These processes are summarized in the next two sections along with observational evidence that addresses the magnitude of the aircraft effect on ozone.

Atmospheric Chemistry

Nitrogen oxides in the UT/LS participate in both ozone-forming and ozone-depleting reaction cycles. The balance

between these processes, and their response to changes in ambient NO_x levels, are sensitive functions of altitude. In the UT region, the primary influence of NO_x is on the production of ozone from CO and CH_4 oxidation. The CO cycle involves the following reactions:

(where M represents a gaseous third body such as N_2 or O_2). An analogous mechanism, which includes the reaction between NO and CH_3O_2 , exists for CH_4 oxidation.

The overall rate of ozone production from CO and CH₄ oxidation decreases generally with height because of decreasing ambient concentrations of CO and CH₄. However, as can be seen from the above reaction sequence, the production rate depends also on the ambient concentrations of NO and OH. For example, increasing OH and NO will increase the rates of reactions [I] and [III], respectively, thereby increasing the ozone production rate. At high enough concentrations of NO_x (>500 pptv) the ozone production rate begins to decrease owing to the increasing importance of NO₂ reactions that remove HO_x species, i.e.,

In the LS region, the primary influence of NO_x is on destruction of ozone by the following radical-catalyzed processes:

(where X = NO, Cl and OH). Increases in ambient NO_x due to aircraft emissions will enhance ozone destruction for the case where X = NO but will decrease ozone destruction for the case X = Cl by removing ClO through reaction [X]:

The exact balance between these contrary effects depends on the background concentrations of NO_x and ClO_x. Throughout most of the year, the net effect of increasing LS NO_x levels through aircraft emissions will be to increase ozone concentrations. An exception is at high latitudes in summer, when NO_x levels are high. In that case, addition of NO_x will decrease ozone.

Increasing NO_x levels due to aircraft exert an indirect effect on atmospheric CH₄ concentrations. This effect is initiated by the formation of OH radicals in reaction [III]. The increased levels of OH in the air traffic corridors lead to decreases in carbon monoxide (CO) through reaction [I]. Because CO lifetimes are longer than NO_x lifetimes, the region of decreased CO concentrations spreads out from air traffic corridors to a much greater extent than do the aircraft NO_x emissions. The CO perturbation spreads all the way to tropical and subtropical regions where much of the global oxidation of CH₄ takes place through its reaction with OH:

As CO levels are lowered in the tropics, OH levels are raised correspondingly. The higher levels of OH serve to lower CH₄ concentrations, which, in turn, lead to a further increase in OH. As a result of the complex interplay (i.e., atmospheric feedback cycle) between NO_x, OH, CO, and CH₄, an increase in NO_x will lead to an amplified decrease in CH₄. The amplification factor is approximately 1.5.

Aircraft emissions of SO_x, H₂O and soot also effect atmospheric ozone concentrations by serving as aerosol precursors. In the UT, sulfate- and water-ice-containing aerosols promote ozone decreases by acting as surfaces for

heterogeneous removal of the ozone precursors NO_x and HO_x. A major identified heterogeneous reaction involves conversion of the temporary NO_x reservoir species nitrogen pentoxide (N₂O₅) into the longer-term reservoir nitric acid (HNO₃).

HNO₃, along with a number of other nitrogen and hydrogen acids and peroxides (e.g., HNO₄ and H₂O₂) are absorbed onto sulfate and water-ice. The absorbed species can be removed from the UT by sedimentation.

In the LS, sulfate- and water-ice-containing aerosol particles not only remove HO_x and NO_x species but also liberate ozone-destroying ClO_x by heterogeneous reactions such as

The net effect of the heterogeneous processes is to decrease ozone in the LS and UT. However, the effect of the aircraft-derived aerosols on LS/UT ozone offsets only partially the effect of the NO_x emissions.

Much less is known about the effect of soot particulates on ozone. Ozone is observed to react directly on laboratory soot surfaces, but the reaction slows as the surface is modified. Heterogeneous reactions of NO_x and nitrogen reservoir species also occur on soot surfaces – in some cases the reactions lead to more reactive species, in others to less reactive ones. Consequently, the effect of aircraft soot on atmospheric ozone concentrations is poorly determined at present.

According to the current scientific understanding, the overall effect of aircraft emissions in the UT/LS is to increase ozone levels. Model calculations indicate that aircraft have increased ozone by about 6% in heavy traffic areas, with an associated 0.4% increase in the total ozone column. In terms of climate effects, the radiative forcing changes due to increased ozone appear to be largely offset by the predicted decreases in methane. Considerable uncertainty is attached to these calculations, however (see Figure 2).

Figure 2 Influence of aircraft emissions on chemical balance in the UT/LS region. Atmospheric chemical reactions couple together O₃, CO, NO_x, and CH₄. Among aircraft emissions, NO_x is calculated to have the greatest effect on the coupled species, acting to increase ambient NO_x and O₃ levels and decrease CO and CH₄.

Observing Ozone Impacts

Dense air traffic in Northern Hemisphere flight corridors will give rise to distinct geographical perturbations of NO_x , aerosols and ozone under two conditions. First, large-scale dispersion of the exhaust must be slower than the chemistry that removes and/or links these emissions to ozone. Second, the strength of the aircraft emissions must be significant relative to other natural and anthropogenic sources of NO_x and aerosols. The total NO_x emission from current global aviation is approximately 0.5 Tg per year, of which roughly 60% is released into the upper troposphere and 15% is released into the lower stratosphere.

The major source of NO_x in the lower stratosphere is chemical oxidation *in situ* of nitrous oxide (N_2O):

The global production rate of NO from N_2O (~ 12 Tg per year) far exceeds that from current subsonic aircraft emissions in the lower stratosphere. Hence there is no expectation, nor observational evidence, that current aircraft are significantly perturbing stratospheric NO_x levels.

In the upper troposphere, the major non-aircraft sources of NO_x include fossil fuel combustion (autos, trucks, etc.), biomass burning, soil emissions, lightning, and N_2O oxidation. Of these, only lightning deposits NO_x directly into the UT. The fractions of NO_x transported into the UT from sources at the Earth's surface or in the stratosphere are small, occurring only during convective events, such as frontal activity or thunderstorms or during stratosphere-troposphere exchange events triggered by meteorological features such as extratropical cyclones. Source strength estimates for the various NO_x sources are listed in (Table 2). As shown in the table, aircraft emissions into the UT are of comparable strength to other sources and contribute a significant fraction of UT NO_x .

Chemical sampling of the UT in and around traffic corridors has revealed each individual aircraft perturbs ambient NO_x levels substantially for distances of several kilometers behind it. At larger spatial scales, aircraft signatures have not been discerned, owing to the high variability of background NO_x . Likewise, there have been no identifiable spatial patterns in ozone concentrations that unambiguously point to production by aircraft NO_x . Long-term ozone trend observations at specific measuring stations (e.g., Hohenpeissenburg, Germany, and Wallops Island, USA), do not correlate with the

growth rate of air traffic from 1970 to the present, indicating that aircraft emissions are not a major factor in the observed upper-tropospheric trends.

Impacts on Clouds

Trails of ice particles – contrails – are the most readily identifiable exhaust signatures of aircraft (*see Clouds and Fog: Contrails*). Contrails often form, even under clear-sky conditions, because aircraft H_2O emissions raise the relative humidity of the air near the exhaust plume above 100%. Water vapor in the supersaturated air subsequently condenses on aircraft-derived soot and sulfate nuclei and freezes to form ice. If the surrounding air is very dry and/or warm, contrails may be short-lived or may not form at all. In either case, the emitted soot and sulfate nuclei will remain in the atmosphere for days and weeks and possibly promote natural ice (cirrus) cloud formation in locations far from the initial aircraft plume. These same nuclei, upon contact with cirrus clouds, may change properties of the cloud particles such as size distribution, number density, and chemical composition.

Like other naturally occurring clouds, contrails and aircraft-induced (or modified) clouds impact the Earth's climate by affecting the radiation balance. For typical particle properties, cirrus clouds trap surface outgoing long-wave radiation more effectively than they reflect solar incoming short-wave radiation. As a result, cirrus clouds tend to warm the climate. However, the magnitude and even the sign of a cloud's radiative effect on climate is a sensitive function of cloud particle size and shape as well as altitude and geographical location.

Cloud Formation Processes

Clouds or contrails can form when air moisture becomes supersaturated with respect to ice. The ice formation process takes place by one of several mechanisms. At higher supersaturations, low-volatility gas phase species will cluster together to form liquid particles. These liquids can subsequently freeze in a process known as homogeneous freezing if the air is cooled by upward dynamical motion. At lower supersaturations, the freezing process may be aided by the presence of a solid particle surface in a process termed heterogeneous freezing. The liquid and solid particles that readily promote freezing and ice crystal growth are typically in the 0.05–1 μm diameter size range; they are referred to as cloud condensation nuclei (CCN) and ice nuclei (IN), respectively. Aircraft emissions may enhance the frequency of these freezing events by increasing the abundances of CCN and IN.

Aircraft soot emissions have attracted attention as a possible source of IN in the UT. The median size of a fresh aircraft soot particulate is approximately 0.02 μm . In order for a soot particulate to become an IN it must be activated (i.e., become more hydrophilic) by reaction with suitable species. Lab studies have shown that acids such as H_2SO_4 induce this activation but that others such as HNO_3 do not. Hydrated samples of soot have been obtained from

Table 2 Present-day sources of NO_x in the troposphere and their approximate strengths

Source	Emission rate (Tg yr^{-1}) Total	Emission rate (Tg yr^{-1}) 9–13 km altitude band
Aviation	0.5	0.3
Fossil fuel combustion	22	0.7
Biomass burning	8	0.2
Soil emissions	7	0.2
Lightning	5	1
N_2O oxidation	12	0.6

Figure 3 Calculated time evolution of the ‘apparent’ emission indices of aircraft-generated particles for various size thresholds. Solid and dashed lines are for low and high ambient aerosol conditions, respectively. Appreciable concentrations of CCN size particles (>50 nm) are predicted only for low ambient aerosol conditions. Adapted with permission from Yu F and Turco RP (1999) *Geophysical Research Letters* 26: 1703–1706. Washington, DC: American Geophysical Union.

non-sulfur-containing flames, indicating the presence of other, as yet unidentified, activating species.

Aircraft emissions of condensable gases such as sulfur oxides and oxygenated hydrocarbons can contribute to CCN formation. In an aircraft plume, large numbers ($\sim 10^{16}$ particles per kilogram of fuel) of small particles (<0.01 μm radius) are formed from nucleation of sulfuric acid and water. The formation and subsequent growth of these particles may be accelerated by chemi-ions that are emitted into the plume following their production in high-temperature reactions occurring in the combustor. As the plume expands and is diluted by entrainment of ambient air, the small plume particles may continue to grow by uptake of additional gaseous species or they may be scavenged by larger ambient particles. The competition between these two processes depends on a number of environmental variables such as air temperature, relative humidity, and background aerosol concentration. Under low background aerosol conditions, such as exist during wintertime, a significant number of plume particles are expected to survive long enough to grow to CCN size (see [Figure 3](#)).

Addition of aircraft-derived CCN and IN to the UT will increase cirrus cloud occurrence in areas where the air is supersaturated with respect to ice but crystal growth is limited by a lack of sufficient numbers of nuclei. Relative humidity measurements taken in the UT reveal that ice supersaturation occurs in more than 10% of the clear-sky cases examined. Cloud growth in these regions should be particularly susceptible to aircraft IN and CCN. In areas of developing cirrus clouds, aircraft-derived CCN and IN may influence the properties of the cloud particles in one of several ways. If the aircraft particles are larger and function as more active growth

nuclei than ambient particles, they may compete effectively for the available water vapor and induce growth of larger ice crystals at the expense of crystal number density. If, on the other hand, the aircraft particles increase the number of CCN and IN, but do not change the overall rate of crystal growth, then increases in the crystal number density are expected, with concomitant decreases in average crystal size. The radiative properties of the resulting clouds will be altered, but the magnitudes and characteristics of these modifications are uncertain.

Observing Cloud Impacts

Cirrus cloud coverage, as documented by surface and satellite observations, has been increasing over a number of regions in the last two decades, with the largest increases observed over regions of heavy air traffic in the United States and the North Atlantic. Growth of cloud cover in air corridor regions has been approximately 1–2% per decade greater than in other areas; attributing this growth rate to aircraft impacts implies that there has been an overall 5% increase in traffic route cloud cover during the last 30 years of air travel. Contrails are clearly a significant part of this increase. For instance, analysis of satellite images has indicated that contrail coverage over Europe is on the order of 1%.

Indirect effects of aircraft-derived aerosols on cloud formation may be responsible for the rest of the observed increase. However, a number of other natural and anthropogenic causes such as changes in UT temperature and humidity, greenhouse gas concentrations, and upper-atmosphere dynamics may be

Table 3 Ozone and climate impacts of present day aviation. Radiative forcing is used as a measure of the climate impact

Impact	Ozone column (% change)	Radiative forcing ($W\ m^{-2}$)
CO ₂		+0.016
NO _x	+0.5	+0.024
CH ₄		−0.015
H ₂ O		+0.002
Sulfate aerosol	−0.1	−0.003
Soot particulate	−0.01	+0.003
Contrails		+0.021
Cirrus clouds		≤+0.04

Numbers are taken from IPCC (1999).

contributing to the increased cloudiness. Currently, there is little observational information from which to determine if aircraft are significant sources of CCN and IN. In a few cases, sampled contrail and cirrus cloud particles have contained significant amounts of soot and metals, suggestive of an aircraft influence. But the few direct measurements of CCN in aircraft wakes have yielded concentrations ranging from very low to very high values. Similar types of measurement for IN have suggested that aircraft wakes do not contain large numbers of these nuclei.

Impact Summary: Present and Future

Scientific progress on aviation impacts has progressed to a point where it is providing important guidance to technology and policy decision-makers. Aircraft CO₂ emissions are known to be small but significant contributors to the observed rise in ambient levels, accounting for approximately 2% of the current total anthropogenic CO₂ emissions. In addition, it is now clear that the overall radiative forcing by aircraft is substantially larger, by a factor of 2 to 5, than the forcing by aircraft CO₂ alone. In terms of possible mitigation strategies, this finding underscores the need to reduce many of the aircraft emissions simultaneously or consider tradeoffs in aircraft designs and operational measures. Examples of tradeoffs include the development of more efficient (i.e., emitting lower CO₂) engines at the expense of higher NO_x emissions and/or promotion of contrails, and increases in average flight altitudes to reduce contrail formation at the expense of increased O₃ sensitivity to NO_x. Consideration of these tradeoffs is tempered by the fact that the impacts from aircraft CO₂ are far better characterized than the impacts from NO_x, contrails, and aerosols (Table 3).

The calculated impacts of the current aircraft fleet on climate and ozone are small relative to the natural atmospheric variability and have not been observed. Like climate and ozone impacts of other individual sectors, aircraft emissions represent a small fraction of the total anthropogenic impact. Consequently, detection of the aircraft-specific contribution to climate and ozone change is not possible at present. Future growth of aircraft emissions is related to economic and population growth. Under some plausible high-growth scenarios, aircraft emissions may increase fivefold over the next 50 years and contribute larger fractions of the anthropogenic climate forcing and ozone change. In addition, the possible

introduction of a supersonic aircraft fleet may contribute to significant changes in stratospheric water vapor and ozone. The potential impacts of supersonic aircraft emissions have been studied in the 1970s and again in the 1990s in concert with industry interest in building a fleet of such aircraft. From these studies, the higher altitude (i.e. 16–20 km) release of supersonic NO_x and H₂O emissions is predicted to generally enhance ozone-depleting cycles (reactions VIII and IX) relative to ozone-forming ones (reactions IV), and lead to a net decrease of ozone. The water vapor emissions from supersonic aircraft, occurring predominately in the relatively dry lower stratosphere, are also predicted to contribute to climate warming.

Even if these future subsonic and supersonic scenarios come to pass, detection of specific aircraft climate and ozone impacts will continue to be difficult. Consequently, technology and policy decision-making will have to rely on observations of overall global change along with a robust scientific understanding of aviation effects.

Aircraft Icing

MK Politovich, National Center for Atmospheric Research, Boulder, CO, USA

Synopsis

Aircraft icing is described in terms of its effect on an airplane, its physical characteristics, associated meteorology, and means to detect and diagnose the icing environment. Diagnosing and forecasting icing require understanding of the physical processes governing icing products, recognizing how these processes relate to observable phenomena, and combining information from as many sources as possible to accurately depict relevant characteristics of the icing environment.

Introduction

Aircraft icing is the accretion of supercooled water onto an airplane during flight. Accreted ice adversely affects flight, thus, it is an important component of an aviation weather forecast. Meteorology associated with inflight icing begins with the microscale, addressing growth of water drops and their collision with and adhesion to airframes. Cloud-scale and meso-scale processes control the amount and distribution of water drops while synoptic weather patterns, which produce what was generally referred to as 'weather', govern the location and movement of icing environments. Diagnosing and forecasting inflight icing involve the development and use of numerical weather prediction models as well as *in situ* and remote sensors. Carburetor icing and precipitation or frost adhering to the wings of an airplane prior to takeoff are not covered here.

Effect on an Airplane

Meteorologists, aerospace engineers, and pilots need and want information about icing because it can adversely affect the flight characteristics of an aircraft. Icing can increase drag, decrease lift, and cause control problems. The added weight of the accreted ice is generally a factor only for light aircraft.

Aircraft can fly safely in icing conditions, but to do so legally they must complete a certification process. To certify a particular type of airplane, it must be flown in a range of natural icing conditions and demonstrated that these conditions result in no significant effect on the airplane's ability to fly. The range was developed from measurements obtained in the 1940s and is illustrated in the accompanying figure, which was designed to envelop 99.9% of icing conditions found in stratiform clouds (Figure 1). More recent studies have confirmed that these provide reasonable limits for certification, although they do not address the problem of large supercooled drops (such as freezing drizzle or rain) or mixed-phase (supercooled liquid drops and ice crystals) conditions.

Certified aircraft are commonly equipped with devices that either prevent ice from adhering to the airframe or remove it once it has been adhered. Such anti- or de-icing equipment can either be deployed manually or through an automatic system triggered by an icing detection probe and includes pneumatic 'boots', heat, and liquids. These are usually applied to the leading edges of the wings and tail and occasionally to the propellers.

Tailplane icing is a subset of icing and refers to icing that accretes on the vertical and horizontal stabilizers of specific airplane types. It is not necessarily caused by unique atmospheric conditions, but is usually referred separately because it results in vastly different response of the airplane than does icing which affects the wings. Thus, pilots require special training for this hazard.

Icing tends to affect general aviation more than commuter or air carrier operations. The smaller aircraft included in the general aviation category tends to fly at lower altitudes where icing is more prevalent. Those aircraft may have less deicing capability and reserve power in case of encountering icing conditions, and their pilots may have less experience operating icing. Air carriers tend to quickly penetrate icing-bearing clouds on ascent and descent from airports and cruise at altitudes far above those where icing resides. Commuter aircraft are caught in the middle both in terms of their ability to handle ice and the altitudes they fly.

Icing Severity

Icing is currently classified into four severity categories: trace, light, moderate, and severe. The most important atmospheric parameters determining severity are the liquid water content, outside air temperature, and drop size. The more water there is, the more is available to accrete on the airframe, thus higher liquid water contents are usually associated with more severe conditions. Temperature influences what happens to that liquid once it impacts the airframe – either it freezes in place or

Figure 1 Icing envelopes defined by liquid water content, drop size, and temperature. From FAA Federal Aviation Regulations Part 25, Appendix C.

runs aft along the surface before freezing to unprotected areas. Drop size controls the collection efficiency of those drops onto the airframe. Drop size is not as important as liquid water content or temperature in determining severity until drops reach drizzle sizes, with diameters exceeding $\sim 50 \mu\text{m}$. Research is being conducted to determine appropriate limiting values for these parameters to define severity categories. The definitions must relate atmospheric conditions to observable information as well as effect on flight in order to be useful.

Types of Icing

There are two main physical types of icing: glaze and rime. Mixed icing is a combination of the two. Rime ice is brittle and opaque and tends to grow into the airstream. It is formed as the drops freeze immediately upon impact. Glaze icing, sometimes referred to as clear icing, can be nearly transparent and has a smoother surface, sometimes with a waxy appearance. It is formed when the drops deform and/or flow along the surface prior to freezing. Glaze icing can be more serious to the aircraft than rime since it tends to run back along the airframe, covering more surface area than rime icing, perhaps flowing and adhering to unprotected areas. Glaze icing also can be hard to see from inside the aircraft and the pilot may be unaware of ice buildup. Mixed icing often occurs in layers, as a transition from rime to clear conditions is encountered. These icing types are illustrated in Figure 2.

The type of icing is related to the air temperature, the liquid water content, and the size of the drops. Glaze (rime) is generally associated with higher (lower) temperatures, higher (lower) liquid water contents, and larger (smaller) drops. There are also effects dependent on the airplane itself, including its wing shape and airspeed.

Location and Frequency of Icing Conditions

Icing-related fatal aircraft accidents average ~ 20 – 40 per year in the United States, with the highest incidence in the winter months. Alaska has by far the highest accident rate, followed by the Northwest, Great Lakes, western Pacific states, and the central United States. In North America, icing conditions are most common along the Pacific Coast from Alaska to Oregon and in a large swath from the Canadian Maritimes to the Midwest. Prime locations migrate seasonally, moving south in the summer and retreating to the north in winter. Figure 3 shows latitudes and altitudes conducive to icing in mid-winter in the northern latitudes; those altitudes at which small general aviation and commuter aircraft fly have more exposure to these environments than transport-category aircraft with higher cruise altitudes.

The average altitude of pilot report of icing is $\sim 10\,000$ ft MSL, with few encounters above $20\,000$ ft. Frequency of icing encounters by aircraft based on time of day is a direct reflection of the frequency of flights, with few reports overnight. The

Figure 3 Temperature versus latitude and altitude, based on a Standard Atmosphere for January. Geographic locations, typical flight altitudes and favored temperature for icing conditions are indicated.

weekly pattern also follows air traffic trends, with most reports on Tuesday through Thursday.

Light icing is the most frequent severity category reported by pilots, ~60–70% of all reports. Severe icing, which indicates a condition which cannot sustain flight, is reported only a few percent of the time. Rime icing is reported much more frequently than glaze or mixed, comprising ~70–75% of reports. For both icing type and severity, the largest joint frequency is for light rime icing, which covers nearly half of all reports.

Relation of Icing to Weather Features

The presence of supercooled liquid water in clouds results from production and depletion processes.

- **Production:** Liquid water is produced by bringing the air to >100% relative humidity (supersaturation), which usually results from cooling the air by lifting.
- **Depletion:** Liquid is depleted by mechanisms that erode the cloud, such as entrainment of dry air, or through precipitation processes. In the majority of mid-latitude clouds and storms, the precipitation process is heavily dependent upon the ice phase.

Regions ahead of or near surface warm fronts are favorable icing regions since they provide widespread lifting of generally moist air. Cold fronts also provide opportunities for icing, with narrower bands of more intense lift near the surface front. Moist, maritime air masses are associated with higher frequencies of icing conditions, whereas continental air masses, especially those well behind arctic fronts, have fewer reports. Topography also influences icing, providing a local source of

lift. For example, cold fronts progressing southward through the central United States often provide widespread icing conditions along the front range of the Rocky Mountains from Wyoming through New Mexico. In these situations, which may also occur along the Appalachians in the eastern United States, cold, moist air is forced up the gentle slope leading to the steep mountain range. Or, orographic clouds may be isolated and associated with mountain peaks and ridges.

Precipitation-forming processes tend to deplete liquid water from clouds. Once drops reach a diameter of $\sim 20 \mu$, they begin to collide with one another and coalesce. The increased mass of the resulting larger drop subsequently increases its fall speed, leading to more collisions, etc., depleting the liquid that existed in small drops as it falls out of the cloud. Similarly, once ice crystals are formed in a cloud, they also fall and collect cloud drops in a process referred to as riming. This tends to deplete liquid – much like the accretion of the supercooled drops onto an airplane.

Although it is often assumed that icing will not be present aloft where there is significant precipitation at the surface, examinations of pilot reports of icing have not borne this out. Chances are about even that one of these reports will be associated with surface snow or rain as opposed to no precipitation. If lift within a cloud is strong enough, water can still be condensed onto existing drops, or new drops may be formed, thus continuing the icing condition.

Icing from 'Cloud-Sized' Drops

Measurements of the microphysical characteristics of icing environments have been obtained from the 1940s through the present. Even though a variety of instruments have been used for these measurements, the data sets form a fairly consistent picture of the icing environment. Temperatures range from 0°C to less than -25°C , with a mean around -10°C . Few icing encounters (≤ 4 –10% depending on location) occur at temperatures below -0°C . At temperatures $\geq -5^\circ\text{C}$, adiabatic compression may increase the actual temperature along the leading edges of the airframe to above freezing (typical dynamic heating corrections are 1 – 2°C for small, slow aircraft, to as much as 6 – 8°C or more for large, faster-flying air carriers).

In convective clouds, 90% of the liquid water contents are <0.5 – 0.7 g m^{-3} and for stratiform cloud <0.3 – 0.5 g m^{-3} . Maximum values are typically ~ 1.2 – 1.3 g m^{-3} but can reach higher values in deep convective clouds. Variations occur for different data sets used in the reported analyses.

Drops are typically small, with average mean diameter or median volume diameter (both are used in icing characterization) usually between 10 and $20 \mu\text{m}$. Maximum values for drop sizes are 30 – $50 \mu\text{m}$, depending on the data set. Cumuliform clouds tend to have larger drops than stratiform clouds, and clouds in continental areas have smaller drops than maritime areas. Liquid water content and drop size generally increase with altitude in single cloud layers, but the behavior is less predictable in multi-layered clouds. These are general guidelines since individual clouds vary considerably from one another and variations within clouds occur.

It is not the case that larger cloud drops, and thus greater icing hazards, are usually found lower in the cloud. The cloud top, in most cases, will have the greatest icing potential. In a rising parcel of air containing cloud drops, the drops grow with time and altitude if supersaturation is maintained. Generally, well above cloud base no new drops are formed so any excess vapor condenses on the available drops and they grow. Thus, larger cloud drops and greater liquid water content are generally found higher in the cloud although there will be exceptions based on the thermodynamic structure of the atmosphere and the lifting mechanism.

Supercooled Large Drop Icing

Supercooled large drops (SLDs), which are those with diameters exceeding 50 μm , can pose an especially serious threat to flight. Their larger size means that they are not as likely as small drops to be carried around the airframe with the airstream but will more readily impact on the airframe. They can impact farther aft than small drops, or flow along the aircraft surface before freezing, which means that they may accrete onto areas not usually protected by de- or anti-icing devices. Roughness resulting from this type of ice accretion can create a high amount of drag. Cases of increased performance degradation due to flight in SLD conditions are well documented from research aircraft.

There are two general situations for formation of SLD. The first is the classic freezing rain process, by which snow forms aloft, falls into an intruding warm ($T > 0^\circ\text{C}$) layer, melts, continues to fall into lower cold air ($T < 0^\circ\text{C}$), and becomes supercooled, ready to adhere to an airplane. This is a relatively easy forecast problem since it requires a specific thermodynamic profile. The other general case is the formation of SLD by coalescence of liquid drops and is not so easily recognized using operationally available data sets. Wind shear (differences in wind speed and/or direction) at cloud top in stratiform clouds may encourage the formation of SLD there. There is some evidence that minimum thresholds of liquid water content must be exceeded for drizzle formation to occur; 0.2–0.25 g m^{-3} in continental and around 0.1 g m^{-3} in maritime clouds. This difference emphasizes the need for the inclusion of realistic regional microphysics parameterizations in numerical weather prediction models.

The observation of freezing precipitation – freezing drizzle, freezing rain or ice pellets – at the ground can provide an important clue for SLD conditions aloft. This makes physical sense since all three are supercooled (or already frozen) large drops – if they are present at the surface, they must be present for some depth above the surface. The more difficult part of using this to diagnose SLD conditions aloft is to determine how far aloft the SLD extend. Knowledge of the moisture and thermal structure of the atmosphere are needed to infer this depth.

Mixed-Phase Conditions

The data used to construct the icing certification envelopes include little information about whether they were collected in purely liquid conditions or in mixed-phase (both liquid and ice) conditions. More recent data sets indicate that a large fraction of

icing encounters are in mixed-phase conditions and this appears to be the norm rather than the exception. This has implications for remote detection and forecasting. Mixed-phase conditions are usually thought to represent a transitory state as ice crystals will tend to grow at the liquid drops' expense. However, in a case with sufficient moisture supply and updraft speed, enough condensate can be produced for both deposition on ice and condensation on drops to occur.

It is not well understood whether the nature of the ice accretion process is different in liquid or mixed-phase cases. Limited data from research flights do not suggest any difference in effect on flight. Thermal deicing systems may be affected. Even so, environmental data collected in mixed-phase conditions are being analyzed to determine if there is an intrinsic difference between these and the current envelopes. The anticipation is that this characterization of the mixed-phase icing atmosphere will be used to create new certification envelopes for use in these conditions.

High Ice Water Content

Aircraft jet engines may suffer power loss from ingest of high amounts of ice crystals. From information on over 100 engine weather-related power loss events, it was concluded that these events were due to flight through areas of high ice water content associated with deep convective clouds. In addition to the obvious safety concerns, these events can also lead to costly engine repairs. Research has recently begun on characterizing the microphysical properties of these clouds, determining how they may be forecast, and investigating the physical process of accretion in the engine during flight. This information will be used to provide guidance to manufacturers and to develop a new certification rule for engine performance in high ice mass environments.

Detecting Icing Conditions

Pilots generally have a poor view of the aircraft's wings so they commonly use the ice accreting on windshields, wipers, or pitot tubes near the nose of the aircraft to assess the presence and amount of ice. The pilot can also notice changes in aircraft performance due to icing. Onboard icing detectors warn the pilot when ice is accreting on the aircraft. In some cases, these instruments are sensitive enough to provide an early warning before the ice becomes noticeable to the pilot. These airframe-mounted detectors are a fairly mature technology, although new systems are still being developed. Examples of detector types are those that can be flush-mounted on the wing and detect differences in capacitance on the surface or use a vibrating rod protruding into the airstream, which detects the difference in resonant frequency as ice accretes. The advantage of *in situ* systems is that they provide a positive detection of icing conditions. However, they have the drawback that the aircraft must necessarily be immersed in the icing environment, and in many cases that is not a desirable place to be.

The use of remote sensors for detecting icing remains in a relatively young stage of research and development.

Operational weather radar systems such as TDWR (Terminal Doppler Weather Radar: C-band, 5 cm) and NEXRAD (Next Generation Weather Radar: S-band, 10 cm) were not specifically designed for icing detection, but may provide information that, when combined with that from other sources such as numerical weather prediction models, satellite imagery, or surface observations, provides clues to the location and intensity of icing.

Short-wavelength radars (such as K-band, 0.86 cm or W-band, 3 mm) have potential for detecting icing conditions, especially in non-precipitating clouds. Dual- or triple-wavelength systems, using combinations of W-, K-, X-, and longer wavelengths, take advantage in the differences in attenuation of microwave radiation by atmospheric liquid at the different wavelengths.

Dual-polarization radars transmit radio wave pulses with both horizontal and vertical orientations. Comparisons of the orientation of the returned signals provide information on hydrometeor shape and that information can be used to infer whether the cloud contains ice crystals, drizzle, rain, or cloud drops. Used alone, this information can be somewhat ambiguous, especially in the case of mixed-phase clouds.

It has been noted that the regions of freezing drizzle tend to have a more uniform look or texture when viewed by radars. This information could be useful in discriminating between possibly hazardous freezing drizzle (SLD) and benign light snow.

Multichannel microwave radiometers, which passively detect radiation emitted from atmospheric constituents, have also been shown to be useful in identifying icing aloft. Their drawback is that they do not identify the altitudes at which icing exists and whether the detected liquid is supercooled. As with radar data, combining radiometer-based information with that from other instruments can help the forecaster gain insight into the nature of the icing environment.

Multispectral weather satellites have shown to be useful icing diagnosis tools. Algorithms have been developed which use combinations of wavelengths to determine locations of supercooled liquid cloud tops. These algorithms would not diagnose all icing conditions – for example, ice-bearing cirrus may overlie a supercooled liquid cloud and prevent its detection, or a supercooled liquid layer may be present above an all-ice cloud. Methods have also been devised to use microwave data from satellites to quantify the total integrated amount of atmospheric liquid water content over oceans. When combined with numerical weather prediction model outputs, a three-dimensional icing diagnosis can be provided.

Forecasting Icing Conditions

Forecasting inflight icing is the same as predicting supercooled liquid water in clouds – not exactly on the list for undergraduate weather forecast lab! Following a ‘forecast funnel’ process, the forecaster seeks

- Clouds or precipitation
- Right temperature regime ($<0^{\circ}\text{C}$, $\geq -20^{\circ}\text{C}$)
- Lift to create liquid
- Lacking significant ice to encourage glaciation

Understanding the processes that create and deplete liquid, in combination with information about where clouds are expected and the temperature structure of the atmosphere,

should provide a reliable and geographically robust prediction. These concepts can also be incorporated into automated systems, which provide the forecaster with initial guidance – or the non-meteorologist with a reasonable ‘final answer’ of where to expect icing.

With the advent of improved numerical weather prediction models with explicit cloud liquid, there is not only a chance to determine where icing really exists (as opposed to inferring it from smoothed temperature and humidity fields) but to quantify the hazard in terms of icing type and severity. Generally, microphysical parameterizations are first developed on research models. Concepts are then coded and tested for use in the operational versions deployed by the National Centers for Environmental Prediction (NCEP). In most operationally run models, the microphysical characteristics are heavily parameterized with idealized size distributions, and conversion of cloud liquid water to drizzle and rain is based on total liquid mass thresholds. New methods to explicitly represent physical processes with computational efficiency are being tested; the resulting size distributions of drops will increase the accuracy of forecasting the icing environment. Additionally, current operationally available models use spatial resolutions that do not resolve potentially significant fine-scale features. These larger scales (typically at least 20 km with hourly output) may work well for strategic preflight planning, but are not effective for tactical use such as ‘weather-in-the-cockpit’ displays. Considerable effort is being put into increasing resolution to 2–3 km, which will allow more realistic cloud physics treatments thus, presumably, leading to more precise icing forecasts.

No one observational tool or weather prediction model provides people with all they need to know about where icing is or is not located nor any of its attributes such as type or severity. Each information source provides one part of the picture. Forecasters combine this information to get the complete story on icing; it makes sense to develop automated algorithms to accomplish the same goal. Automated versions of this human technique have been developed and to date have proved quite successful in diagnosing where icing conditions reside, their expected severity, and the probability of encounter. The key to successful icing forecasting lies in understanding the physical processes resulting in supercooled liquid water production, how these processes relate to observable phenomena, and how to combine information from as many sources as possible to gain the most complete picture of the icing situation.

Supercooled Large Drops

Supercooled large drops, those drops having diameters exceeding 50 μm , can be extremely hazardous for some types of aircraft. These papers describe the hazard, weather conditions conducive to large drop icing, and the weather associated with the accident. The accident described by Marwitz et al. (1995) was a turning point in icing research as it found supercooled large drop icing was a factor in the accident, which killed 68 people. This opened up a new area of research focused on characterizing the environment and initiated work on new regulations regarding certification of aircraft for flight into such conditions.

This article is reproduced from the previous edition, volume 1, pp 166–177, © 2003, Elsevier Ltd.

Introduction

A broad range of aviation weather hazards affect operations from takeoff and landing to in-route flight at high altitudes. A goal here is to provide an overview of key meteorological processes disrupting flight, reducing lift, increasing drag, influencing instrument readings, or reducing visibility. These atmospheric factors include gravity currents including thunderstorm gust fronts and sea breeze fronts. Because the motions and decay of aircraft wake vortices are controlled by local winds, turbulence, and stability, these dangerous wake effects are also discussed. Hazard types covered appear in [Table 1](#), together with brief descriptions of their potential impacts on flight. [Figure 1](#) summarizes some of these meteorological disturbances, indicating typical flow strengths and altitudes affected. Encounters with turbulence aloft can disrupt flight paths and cause injuries to crews and passengers. Such strong encounters can result from organized instabilities of limited duration or extent, such as breaking gravity/shear waves. On the other hand, more random turbulence aloft, when of long duration and covering extended areas, can contribute to structural fatigue and reduce aircraft operating lifetimes.

For selected hazards, atmospheric causal processes are reviewed and key properties such as dimensions and strengths are summarized. Also, discussions of efforts at hazard prediction, detection, and warning illustrate the progress that has been made in mitigating atmospheric impacts on the aviation system.

Atmospheric Gravity Currents

One important type of atmospheric gravity current is the outflow from a distant thunderstorm downdraft. For these systems, because the downdraft region is usually quite large in

Figure 1 Summary of the altitude impact ranges of meteorological hazards and typical wind speed strengths involved.

diameter (typically 10 km or more), the wind shears near the downdraft can be relatively weak. However, the wind speed and wind direction change that accompany the leading edge can cause significant relative air speed changes for aircraft.

Sudden aircraft performance changes caused by the atmosphere (whether increasing or decreasing performance) are problematical. [Figure 2](#) is a conceptual view of a gust front from a distant thunderstorm crossing an airport. Although at times these boundaries are clearly visible because of entrained dust, more often the boundary will occur invisibly in clear air at large distances from the originating thunderstorm.

The speed of motion, c , of a gravity current with no ambient wind can be estimated from the density current equation [1].

$$c = Fr \left(\frac{\Delta T}{T} gh \right)^{1/2} \quad [1]$$

Table 1 A summary of aviation weather hazards and their areas of impact upon flight operations

Hazard	Areas of impact
Atmospheric gravity current wind shears (e.g., thunderstorm gust front and sea breeze front)	● Relative air speed changes ● Require runway changes
Microburst wind shears	● Flows can exceed performance capabilities of modern aircraft
Vertical wind shear	● Deviations from glide slopes
Gravity/shear waves	● Flight disruption and structural fatigue ● Increased drag and reduced lift
Icing	● Reduced stall angle
Terrain-induced disturbances (e.g., lee waves, rotors, bora)	● Flight disruption ● Deviations from assigned flight altitudes ● Structural damage
Vicinity of thunderstorms (e.g., hail, funnels, obstacle flows)	● Flows can exceed performance capabilities of modern aircraft ● Deviations from flight altitudes ● Structural damage
Aircraft wake vortices transported to unexpected locations	● Roll moments disrupting flight of following aircraft
Altimeter errors	● Deviations from assigned or expected flight altitudes

Figure 2 Conceptual view of a gust front from a distant thunderstorm crossing an airport.

Here, Fr is the Froude number (~ 1), ΔT is the temperature change in the gust front air relative to the environmental air, T is the mean temperature, g is local gravity, and h is the height of the outflow boundary. Corrections for the ambient wind can be made. [Table 2](#) summarizes statistics for gust fronts measured in the Denver, Colorado, region during an intensive field program during the summer of 1982. Data from this and other experiments demonstrate that the density current equation applies quite well. The leading edge is usually accompanied by a temperature drop and pressure rise, unless complicated by the existence of a ground based inversion layer. [Figure 3](#) shows an acoustic sounder display of a gust front propagating on top of a ground-based inversion.

Another important aspect of thunderstorm outflow boundaries is that a preferred region for the initiation of new convection is near the leading edges where vertical forcing of ambient air occurs. This is especially true where boundaries collide. Microbursts also have a tendency to occur near outflow boundary regions. Fortunately, Doppler radar can detect these gust front boundaries effectively and provide an invaluable,

allweather resource to guide airport operations when gravity currents are approaching.

Microbursts

Between 1964 and 1985, over 30 commercial aircraft crashes resulted from microbursts. A microburst is defined as a downdraft region with a scale size less than 4 km. The resulting strong outflows usually do not travel radially outward for long distances (>10 km), and the durations are short (often less than 10 min). However, in the vicinity of a microburst, strong winds ($> 50 \text{ m s}^{-1}$) and rapid wind direction changes of 180° can occur. When microbursts descend near or on runways, they constitute an extreme flight hazard. Microburst flows are analogous to those produced when squirting a water hose on a flat surface. The downflow jet interacts strongly with the surface, producing strong radially directed flows. The large spatially concentrated horizontal wind vector changes and the downdraft can produce increasing performance/decreasing performance couplets that are difficult to predict and handle. For example, an aircraft flying through a microburst that has impacted the approach end of a runway will first encounter a head wind, increasing performance and causing excursions above the glide slope. As the pilot corrects for this, the aircraft enters the downdraft region, followed by an outflow region, rapidly degrading performance. Depending upon the timing and relative positions of the aircraft and microburst to the runway, this scenario can be catastrophic. The timing is so critical that even landing differences of several minutes can be important. The statistics of microbursts measured in the vicinity of Denver, Colorado, are presented in [Table 3](#). Microbursts were identified by the winds clearly radiating outward from a center, as distinct from the essentially linear gust front winds. To date, the largest wind speed documented for

Table 2 Gust front statistics derived from surface meteorological stations in the Denver, Colorado region during the summer of 1982. Number of events = 99

Parameter	Average	Minimum value	Maximum value
Wind speed change	9.4 m s^{-1}	3.0	17.0
Wind vector change	13.7 m s^{-1}	5.0	37.0
Temperature change	-1.9°C	-5.1	+3.1 ^a
Pressure change	0.67 hPa	-0.4 ^a	3.3
Rain rate	24 mm h^{-1}	0	3.0

^aThese anomalous readings of temperature increase and pressure decrease resulted from the passage of a gust front on top of and eroding a ground-based inversion.

Figure 3 Acoustic sounder detection of a gust front propagating on a ground-based inversion.

a microburst was that related to a 'near miss' of Air Force One with President Reagan on board when it was on the ground near Washington, DC, on 1 August 1983 (a wind speed surge over 60 m s^{-1}). The microburst occurred five minutes after the plane landed. Newspaper accounts said that a secret service officer jumped on top of the president to protect him as the winds buffeted the aircraft.

There are two extreme types of microbursts: 'dry' and 'wet'. Dry microbursts are especially hazardous because the visible virga (raindrops or a snow plume descending from cloud base as in the photograph in Figure 4) related to the microburst initiation process evaporates and becomes invisible as it approaches the surface. Since the downdraft descent time takes about 5 min, it can be difficult to relate an observation of virga to a resulting microburst. Conversely, a wet microburst has a strong rain shaft and is easily seen if not obscured by rain from a surrounding storm (Figure 5).

Doppler radar can detect microbursts once the radial outflow is established by the intense downdraft penetrating to the surface. Also, the concentrated rain shafts for wet microbursts can be detected. The uses of arrays of airport wind sensors, Doppler radars, and improved controller/pilot training

(both to recognize visual clues and to respond in the best possible way if a microburst is encountered) have helped to reduce microburst-related accidents. Also, the fact that the lapse rate between 500 and 700 hPa is correlated with microburst probability provides forecasting potential for dry microburst likelihood. Dry microbursts are more probable when the lapse rate is $> 8^\circ\text{C/km}$.

Vertical Wind Shear and Gravity/Shear Waves

Whereas the thunderstorm gust front and microburst hazards result primarily from horizontal changes in wind speed, vertical changes in wind speed and direction can also present a hazard, especially for lower-level flight operations. A ground-based inversion is often accompanied by calm winds near the surface and strong winds just above the cooler, stable near-surface air. Aircraft descending or ascending through such layers can encounter strong wind shear-produced performance changes and turbulence, and rapid fluctuations associated with gravity/shear waves. These waves have scale sizes from tens to hundreds of meters, resulting in aircraft interaction times of seconds or less. Figure 6 is a conceptual view of such a situation in the vicinity of mountains. Figure 7 is a Doppler lidar display of gravity/shear waves. Vertical wind shear conditions can be especially important for general aviation airports if relative airspeed is suddenly reduced on a low-level approach or during takeoff in the vicinity of terrain. At airports where wind shear above stable air is a frequent problem, boundary layer wind profilers or acoustic sounders can provide valuable real-time monitoring capabilities.

The presence of gravity/shear wave activity often complicates flight through layers of vertical wind shear. A pure shear layer in a neutrally buoyant atmosphere may be modeled as a vortex sheet, highly unstable to disturbances. If wind shear

Table 3 Impacting microburst statistics derived from surface meteorological stations in the Denver, Colorado region during the summer of 1982. Number of events = 33

Parameter	Average	Minimum value	Maximum value
Wind speed change	13.5 m s^{-1}	2.5	27.5
Wind vector change	20.7 m s^{-1}	10.0	37.5
Temperature change	-1.5°C	-9.0	$+5^a$
Pressure change	0.66 hPa	-1.5^a	2.0
Dew point change		-7°C	$+7^\circ\text{C}$
Rain rate	16.4 mm h^{-1}	0	2.75

occurs in conjunction with a stable layer, gravity provides a restoring force, and such a system will support wave motion. Hence, the term gravity shear wave. Several questions naturally follow from this situation.

- Under what conditions will the upper-level wind shear start to erode the stable air and turbulence grow?
- At what rates do such stable pools of air get removed?
- What are some examples of situations where these processes are important for flight operations?

The Froude number, Fr , is a measure of the relative importance of inertial and gravity forces. For the situation of flow above a stable layer, Fr is given by eqn [2], where U is the flow speed above the inversion, g is local gravity, h is the height

Figure 6 Conceptual view of gravity/shear waves in the vicinity of mountains.

Figure 7 Doppler lidar display of gravity/shear waves in the vicinity of mountains, showing the accompanying wind speed changes. of the inversion, $d\rho$ is the density difference between the two layers, and ρ is the mean density.

$$Fr = \frac{U}{\left(d\rho \frac{gh}{\rho}\right)^{1/2}} \quad [2]$$

In field and laboratory experiments, the start of disturbances and waves takes place when the Froude number exceeds about 0.6. Thus, if the height of the inversion and a temperature profile are available, the threshold speed U can be estimated. Once the erosion process starts, it can often continue at a slow and approximately constant rate. Values of vertical erosion rates near 10 cm s^{-1} have been measured near complex terrain.

On the positive side, the time scales are of the order of hours for changes, in contrast with minutes for microbursts. Thus, vertical wind profilers for monitoring and knowledge of local climatologies can be quite valuable, particularly for mountain valleys and the lee sides of complex terrain.

Another important dimensionless number is the Richardson number, Ri , which is an important index for turbulence. This number depends upon the gradients of both temperature and wind speed (eqn [3]).

$$Ri = \frac{g}{\theta} \frac{d\theta}{dz} \bigg/ \left(\frac{dU}{dz} \right)^2 \quad [3]$$

Figure 8 Photograph showing gravity/shear waves visualized by cloud formations.

Figure 9 A summary of situations contributing to aircraft icing events. SLW stands for supercooled liquid water.

In eqn [3], g is local gravity, θ is the mean potential temperature, $d\theta/dZ$ is the change in potential temperature with height, and dU/dZ is the change of wind speed with height. The criterion for turbulence, $Ri < 1/4$, has been shown to be a valuable index for aircraft turbulence when temperature and wind speed profiles are available to make the comparison between predicted turbulent altitudes and actual turbulence reports from pilots. A challenge is either to predict the temperature and wind speed gradients or to measure them with sufficient accuracy to produce reasonable estimates of Ri values. Wind profiling radars used in conjunction with the Radio Acoustic Sounding System (RASS) to obtain temperature profiles will be valuable for such applications. Pilot reports as well as the use of visual clues are also an

invaluable component for avoiding regions of turbulence aloft. Figure 8 depicts gravity/shear waves that are revealed by cloud formations.

Large-amplitude, long-lived gravity waves represent another aspect of the hazard. Such waves have been observed to propagate rapidly (at $35\text{--}40\text{ m s}^{-1}$) away from the region of a cyclone where they were generated. The waves in this case traveled through eastern New England in the United States. The high-speed waves were accompanied by precipitation and wind surges. For example, at Boston the wind increased from less than 10 knots to 57 knots over about 5 min. Such discontinuities can represent significant hazards, since they are unexpected weather features producing wind vector changes on scales that can affect flight, especially during takeoff and landing.

Icing

Icing potential depends upon the probability of drops of supercooled liquid impacting aircraft surfaces. Larger droplets are more likely to strike an airfoil, since they do not easily follow the flow streamlines and pass around an obstacle as do smaller droplets. The icing hazard can be insidious because of two factors:

1. Only a small amount of ice deposition can have large, deleterious effects upon lift and drag, thus reducing aircraft performance.
2. Icing and the degradation of performance can increase slowly and imperceptibly, until an emergency exists.

Two situations account for most reported in-flight icing encounters. Convective activity involves relatively large amounts of supercooled liquid water, and the hazard can extend to higher altitudes with the potential of significant ice accumulation in a short time.

The other frequent situation involves flight through layered cloud decks. Although the supercooled liquid content can be lower than in convective situations, aircraft typically spend more time in these layered clouds, accumulating significant ice on fuselage and control surfaces. [Figure 9](#) depicts situations contributing to this form of icing, which is especially important for commuter and general aviation aircraft operating at lower altitudes. The wind shears and turbulence often accompanying such systems can be regions where larger drops are concentrated by mixing. Sometimes, by making small altitude changes, a plane can avoid these regions of enhanced icing potential.

Combinations of remote sensors have value for the monitoring and forecasting of icing situations. Polarimetric radars, dual-wavelength radars, wind profilers, RASS, and passive

radiometric measurements can, in concert, indicate the locations of supercooled liquid. Aircraft can also accumulate icing on the ground in freezing rainstorms. This problem is treated at major airports by application of de-icing fluids before takeoff (see [Aviation Meteorology: Aircraft Icing](#)).

Terrain-Induced Turbulence

Terrain effects can occur at all flight levels, with some disturbances affecting the stratosphere. The flow situations can range from lee waves, bora flows (a form of density current), and rotors, to mechanically induced turbulence. [Figure 10](#) is a Doppler lidar display showing the roll-up of a vortex sheet in the Colorado Springs area. At times, organized instabilities can occur in the forms of vertical or horizontal axis vortices. These obstacle-involved situations can be exceptionally complex when the terrain flows interact with other meteorological factors (such as lee-side inversions). Since 1964, there have been 15 major accidents and incidents in the vicinity of complex terrain ([Table 4](#)).

One study indicated that the general aviation accident rate was 40% higher for US mountain states than for all other continental states, and the rate was 150% higher for a selected group of mountain airports relative to a group of nonmountain airports.

[Table 4](#) indicates a pattern of sporadic encounters of aircraft with severe or extreme turbulence in the vicinity of mountains. In many cases, aircraft preceding or following the aircraft involved in the event encountered some turbulence, but not the extreme turbulence of the encounters (which often exceeded structural limits). Thus, the regions of severe or extreme turbulence may, at times, be spatially concentrated and short-lived. This makes predicting the time and location of these events more difficult. There is a great need to define the properties of mountain-related hazards, improve short-term

Accident	10 Jan. 1964	East of Sangre de Cristo mountains in New Mexico	B52, wind rotor suspected

forecasting of these events, improve pilot training resources, and develop detection methods.

Major field experiments have addressed this problem, which requires three-dimensional sampling of large volumes of the atmosphere as a function of time, documenting both surface and near-surface effects, as well as upper tropospheric and stratospheric effects. Both physical scale models and numerical models have guided the execution of field programs studying mountain flows, which require the commitment of considerable scientific and measurement resources. Figure 11 shows an example of the changes in flows encountered by a research aircraft traversing a lee wave in the Rocky Mountain region of the US. Similar strong changes were also encountered in temperature, pressure, and vertical wind speed, with great

differences as a function of horizontal distance and flight level. Doppler lidars have the ability to detect these hazards near the surface in clear air. Figure 12 is a Doppler lidar display illustrating the complexity possible for such upper-level mountain flows.

Thunderstorms

The most extensive study of thunderstorms was the Thunderstorm Project. This study included surface meteorological stations, soundings, radar, and numerous aircraft flights. This study not only treated the larger-scale thunderstorm structure, circulation, and surface effects, but also properties important for

Figure 11 Horizontal wind speed changes encountered by a research aircraft in a lee wave situation on 25 January 1984. Data from flight legs at four altitudes are shown.

Figure 12 Doppler lidar display showing rotor circulation associated with lee waves. The numbers below the color bar are the radial wind speeds in meters per second. The numbers above the color bar are the distance in kilometers from the lidar. Courtesy L. Darby, NOAA.

flight. These thunderstorm effects influencing aircraft included turbulence, hydrometeors, downdrafts, and updrafts, providing statistics for these thunderstorm parameters. The report also discussed the thunderstorm structure as detected by radar and geographical/topographical effects on thunderstorm development. This report by Byers and Braham is an important resource addressing all aspects of thunderstorms (see [Further Reading](#)).

Radar guidance permits aircraft to navigate gaps between growing thunderstorm cells, and it is presumed here that pilots will avoid penetrating such violent severe weather directly. On the other hand, the clear air around cells or near benign-looking flattened anvil clouds often appears safe for flight, but these regions should be approached with caution if they cannot be avoided. [Table 5](#) outlines these regions near thunderstorms and some of the potential hazards.

Aircraft Wake Vortices

The strong vortex pairs behind heavy aircraft flying at low speeds result from the lift being generated. The tangential winds near the cores can be greater than 100 m s^{-1} (measured

at over 130 m s^{-1} for a Boeing 757). In an ideal atmosphere (neutrally stable, with no winds or turbulence), these vortices move downward and then outward, diverging in a predictable way as they approach the surface of the Earth.

However, with light wind speeds that are close to the transport speeds of the vortices, complex vortex trajectories can result. [Figure 13](#), from numerical simulations, shows how vortex transport can be modified by ambient winds and for some situations can remain stationary over runways. Such motions have been documented in field experiments. In addition, atmospheric stability also affects transport, perhaps causing the vortex pair to remain at a higher altitude than expected. The level of atmospheric turbulence is an important factor in controlling vortex decay times. Although generated by aircraft rather than being a true atmospheric meteorological phenomenon, it is the variability of the atmosphere that magnifies the hazard potential.

Concern about the wake vortex hazard to following aircraft is a limiting factor for the most efficient use of airport operations. This is because safety is currently ensured through the use of increased spacing between heavy aircraft and following aircraft. In spite of this, between 1983 and April 2002 there

Table 5 Atmospheric hazards near thunderstorms

Potentially hazardous region	Comment
1. Clear air regions to the lee of thunderstorms acting as obstacles to ambient winds	Aircraft upsets have been caused by lee waves around thunderstorms
2. Funnels may occur in the vicinities of anvil regions	There have been funnel-related aircraft accidents
3. Near or in the tops of weak-looking convective cells when there is wind shear present	These situations can strengthen regions of concentrated vorticity
4. Lightning strikes in and near thunderstorms	Frequent occurrence; damage can affect flight performance and cockpit instruments. Composite material airframe structures are at greater risk
5. The clear air above thunderstorm tops is a location for sprites, elves, blue jets and other electromagnetic phenomena	The hazard potential is not known. This may become a factor for aircraft manufactured from composite materials

Figure 13 Computations of aircraft wake vortex transport affected by atmospheric winds.

were nine documented accidents with wake vortices as the cause. Although most of these accidents involved general aviation aircraft encountering the wakes of heavy commercial aircraft during approach or departure, some involved in-route wake upsets between two heavy aircraft. For example, on 2 September 1999 a Boeing 737 out of Santa Barbara, California flew through severe turbulence from the wake of an MD-11, with 15 injuries. This occurred in spite of a separation of 11 miles. In the future, the use of remote sensing technologies to track the positions of vortices could permit more effective use of runways. Also, boundary layer wind profilers and RASS could provide detailed real-time wind and temperature data as inputs to vortex transport prediction models.

Altimeter Errors

There are several critical ways in which altimeter errors can affect the aviation system. Pilots may be at any of three distinct altitudes:

- Where they are assigned
- Where they think they are
- Where they are

Several factors can contribute to these three places not being the same. There could be errors in calibrating aircraft altimeters. There could be malfunctions of aircraft instruments (e.g., clogged pressure ports).

Figure 14 Altitude changes encountered by a research aircraft traversing a lee wave on 25 January 1984. Data from flight legs at four altitudes are shown. These measurements are for the same flight shown in [Figure 11](#).

Table 6 Remaining areas of special need

- Improved knowledge of terrain-induced disturbances and the development of mitigation techniques
- Improved warnings for ‘free air’ turbulence, especially better knowledge of risks in the vicinity of thunderstorms
- Earlier detection techniques for dry microbursts and increased understanding concerning their initiation processes
- Improved warnings of icing situations
- Better predictions of the transport and decay of aircraft wake vortices
- Broader application of site-specific remote sensing technologies for hazard prediction and monitoring applications

Also, the surfaces of constant pressure could be highly perturbed (e.g., by strong lee wave conditions or in the vicinities of frontal boundaries). Atmospheric winds around buildings housing altimeters can cause significant differences between true static atmospheric pressure and a measurement contaminated by dynamic pressure effects. For example, winds between 10 and 25 m s⁻¹ can induce dynamic pressure errors as large as about 2 hPa at an airport barometer (equivalent to altitude errors between 3 and 20 m). The development of new static pressure probe designs and improved calibration procedures is helping with these problems, which can be critical for mountain flying situations.

In the future, deviations from assigned flight altitudes in the vicinity of pressure surface perturbations will become more of a concern. As air traffic continues to increase, so will the motivation to allow smaller vertical separations of flight altitudes. There is a need to document the statistics of these excursions as well as the conditions under which they occur. The significant altitude changes involved with an aircraft traversing a lee wave on 25 January 1984 provide an example of the importance of such encounters (Figure 14).

Concluding Remarks

The early literature of aeronautical meteorology contains vivid accounts of the frightening experiences of balloonists within thunderstorms. Fortunately, the evolution of modern flight has made modern aircraft largely immune to such experiences, but they are susceptible to other hazards, such as microbursts and wake vortices (in part because of our technological advances). On the other hand, modern lighter-than-air vehicles, both

tethered and untethered, can find themselves similarly challenged because of limited agility. The future uses of lighter-than-air craft may be expanded as our ability to make reliable long-range forecasts improves. Table 6 outlines challenges we still face in continuing to mitigate aviation weather hazards. The application of remote sensing technologies, better knowledge of atmospheric dynamics, improved numerical models, and accurate longer-term forecasts will be critical to success.

Acknowledgments

I am grateful to L. Darby of the Optical Remote Sensing Division of the Environmental Technology Laboratory of the National Oceanic and Atmospheric Administration for making available the Doppler lidar images used in Figures 7, 10 and 12. I am also grateful for the valuable suggestions of an anonymous reviewer. G. Salottolo of the US National Transportation Board provided information about aircraft accidents attributed to wake vortices.

Synopsis

The development of the scientific understanding of clear air turbulence (CAT) as an aviation hazard is described in this article. Topics range from the discovery of CAT during World War II to modern techniques to observe and predict conditions conducive to CAT formation. Important physical processes leading to Kelvin–Helmholtz instability (KHI), a primary producer of CAT, are explained. The frequency of occurrence of KHI is shown to be a maximum near synoptic scale upper level frontal zones near jet streams, with mountain waves, and above the tops of severe thunderstorms. Several current physical and statistical approaches to CAT prediction based on this knowledge are described. Finally, climatologies derived from both aircraft observations of CAT and numerical indices correlated with CAT are used to illustrate the global and seasonal distribution of CAT potential.

Introduction

Since the first aircraft flight, pilots have been aware of in-flight turbulence. Because the known turbulence of the time was tied to strong, low-level winds, rough terrain, and convection, some of the early pilots predicted that, with the exception of thunderstorms, the ability to attain higher flight altitude with pressurized cabins would be accompanied by a marked decrease in turbulence. This was not to be. In the 1940s, as fighter aircraft attained tropopause altitudes, they experienced a previously unknown phenomenon: clear air turbulence (CAT), so-called because initial encounters occurred in areas devoid of clouds. As aircraft were designed to fly higher and faster during the last half of the twentieth century, CAT became the focus of many organized research efforts. The knowledge of CAT has grown substantially as a result.

Traditional aircraft turbulence intensity scaling (including CAT) differs from turbulence metrics used in fluids, as they are usually conceived for other applications. Aircraft turbulence is defined in terms of the aircraft response magnitudes scaled to subjective intensity descriptors as perceived by pilots and airplane passengers. Classical turbulence is defined for most applications in terms of the state of the fluid eddy dissipation rate (EDR) or the ratio of turbulent flow speed fluctuations to the fluid flow velocity. Simply put, aircraft turbulence is ‘bumpiness in flight.’ The difference is critical in that bumpiness depends on aircraft design, weight, speed, and pilot input, in addition to the state of the atmosphere (gusts, wind shears, or waves), which may or may not be turbulent in the classical sense.

CAT is now defined as aircraft turbulence that occurs at altitudes of 5.6 km (atmospheric pressure of about 500 hPa) or higher, either in cloud-free conditions or within stratiform clouds. The critical influence of CAT is on flight safety. One of the oldest schemes for the characterization of turbulence intensity is based on deviations in vertical acceleration from the normal acceleration of gravity (1g). These categories and their threshold deviations are light, moderate, severe, and extreme (Table 1).

The physical impact of CAT on crew and passengers varies from discomfort for the lighter turbulence categories to loss of

flight control during the rare extreme turbulence event. In the most intense episodes, injuries, and in some very rare cases, fatalities have occurred. Unrestrained crew and passengers are especially vulnerable. Flight through turbulent conditions also produces stresses on the airframe. Repeated turbulence encounters over the lifetime of the aircraft may lead to metal fatigue and, in extremely rare cases, structural failure.

Causative Mechanisms and Characteristics

The discussion that follows considers atmospheric phenomena that contribute to CAT on a wide range of scales. This section examines briefly the primary physical characteristics and causes of microscale CAT. It then considers macroscale and mesoscale forcing mechanisms that create a favorable environment for CAT development.

Kelvin–Helmholtz Waves and CAT

The understanding of the production of CAT and its characteristics is rooted in theoretical studies of fluid mechanics, laboratory and numerical experiments, and field studies. The evidence from these investigations is that Kelvin–Helmholtz instability (KHI) episodes are the cause of a large fraction of CAT. KHI produces shearing gravity waves with typical horizontal wavelengths of a few tens of meters to a few kilometers, precisely the range of eddy sizes to which most aircrafts will have the maximum response. KHI arises from micro- and mesoscale wind shear intensification when smooth, wavelike oscillations within a sheared, statically stable layer grows in amplitude to the point where the wave crests overturn, or ‘break.’ Wave breaking at wavelengths of hundreds of meters is highly effective in producing CAT, with a rapid cascade of energy from the KHI to smaller scale turbulence and dissipation. With respect to CAT, some of the more important characteristics of KHI are the following:

1. The typical lifetime of an individual KHI is about 5 min.

Table 1 Turbulence categories in terms of vertical acceleration, aircraft response, passenger experience, and EDRs for large aircraft

Turbulence category	Aircraft vertical acceleration magnitude (deviations from g , $m\ s^{-2}$)	Aircraft response	Passenger experience	Approximate (EDR) ^{1/3} ($m^{2/3}\ s^{-1}$) for B737, B757 aircraft
Light	0.2–0.5	Momentarily causes slight, erratic changes in altitude and/or attitude.	A slight strain against seat belts. Unsecured objects may be displaced slightly. Walking possible with little difficulty.	0.1–0.3
Moderate	0.5–1.0	Changes in altitude, attitude, and/or airspeed occur.	Definite strain against seat belts. Unsecured objects are dislodged. Walking is difficult.	0.3–0.5
Severe	1.0–2.0	Large, abrupt changes in altitude, attitude, and/or airspeed. Aircraft may be momentarily out of control.	Occupants are forced violently against seat belts. Unsecured objects are tossed about. Walking is impossible.	0.5–0.7
Extreme	>2.0	The aircraft is violently tossed about and is practically impossible to control. May cause structural damage.	Truly frightening.	>0.7

Reproduced from Lane, T.P., Sharman, R.D., Trier, S.B., Fovell, R.G., Williams, J.K., 2012. Recent advances in the understanding of near-cloud turbulence. *Bulletin of the American Meteorological Society*, 93, 499–515.

- The length of the dominant wave (most unstable KHI mode) is proportional to the depth of the sheared layer (i.e., about six times the depth). However, as KHI-induced turbulence and mixing modify the local wind shear structure and stability stratification, variations in the KHI wavelengths can be expected.
- The intensity of the turbulence produced in individual KHI eddies is proportional to the peak local wind shear generated as the wave amplifies and breaks. If the turbulent mixing caused by KHI sufficiently weakens the background wind shear, the turbulence will decay and the flow will again become laminar. However, if turbulent mixing strengthens the wind shears near the boundaries of the old turbulence layer, then new KHI may develop.

Another relevant result from studies of KHI has been the development of a basic dynamic instability principle for a simple model of shearing gravity waves. Based on linear theory, the Miles–Howard criterion states that unstable wave modes resulting from vertical shear are likely to occur when the local gradient Richardson number (Ri) is less than 0.25. In contrast, if (Ri) becomes 1.0 or more, and KHI is present, they will decrease in amplitude. The use of (Ri) as a practical index for CAT diagnosis and prediction is discussed in a later section.

Although the mesoscale sheared layers in which shorter wavelength KHI occur are, typically, less than 1 km in depth, horizontal dimensions are much larger (i.e., from ~ 10 km to a few hundred kilometers, often elongated in the direction of the wind). Thus, an individual KHI develops over a considerably smaller horizontal scale than the sheared stable layers in which it is embedded. This observation has four important ramifications:

- An aircraft flying in a sheared layer may experience CAT over a distance much greater than the scale of an individual KHI.
- CAT encounters are often burstlike (highly intermittent) as an aircraft crosses a thin sheared layer or as an aircraft flying within a sheared layer intercepts individual KHI elements in different stages of development.

- Regular, comprehensive observations of CAT are difficult to acquire because of its small scale and intermittent nature.
- Conditions conducive to the development of CAT are rooted in larger scale processes that produce and perturb the extensive, sheared stable layers.

Internal Gravity Waves (IGW) and CAT

IGW with horizontal scales of a few kilometers to a few hundred kilometers are also mechanisms for CAT production. IGW may become significant in the production of CAT in several ways. Wave amplitude variations with height are caused by the decrease in density with altitude and by the variation of background stability and wind with height. Aircraft intersecting large-amplitude IGW may be exposed to ‘sharp-edged’ gusts or periodic vertical motions which may be interpreted as CAT. Vertical displacements due to gravity wave motions will modulate background wind shear, leading to the production of microscale KHI. Wave breaking may produce intense turbulence near or somewhat below (~ 1 – 2 km) the ‘critical layer,’ where phase speed and background wind speed are the same. Finally, the occurrence and intensity of CAT are also affected by the excitation of IGW from different sources, as well as by resonant nonlinear interactions between different IGW modes and between IGW and KHI in turbulent layers (see **Dynamical Meteorology: Overview**. **Gravity Waves: Overview**).

Macroscale Forcing

Any atmospheric circulation system that produces deformation and/or convergence in the flow field, differential horizontal temperature advection, or secondary (vertical) circulations has the potential to create and strengthen sloping stable layers and their associated atmospheric stability and wind shear. Because of thermal wind requirements, such layers (also called baroclinic layers or frontal zones) are vertically sheared. Frontal zones are particularly common with extratropical cyclones and associated upper tropospheric jet streams, thus presenting optimal conditions for the development of KHI and CAT.

Additionally, developing extratropical cyclones and jet streaks, as well as sharply curved anticyclonic flows, are characterized by unbalanced (ageostrophic) flow. Under these conditions, accelerations generate a broad spectrum of not only IGW but also longer, inertia-gravity waves which may also be effective in producing CAT by modulating shallow shear layers, as well as by their own instabilities. Because the jet stream environment is optimum for the production of sheared stable layers, about two-thirds of CAT occurrences are found near the jet stream. As a function of height, CAT frequencies reach a maximum near the tropopause, and in the baroclinic zone below the jet core.

Macroscale flow patterns conducive to CAT are shown schematically in Figure 1. They can be classified into four basic types: (1) col pattern, (2) sharp trough, (3) ridge, and (4) negatively tilted trough associated with baroclinic instability. Based on observational studies, flow conditions resulting in anticyclonic shear or curvature (such as pattern (3), Figure 1) produce CAT most frequently, while cyclonic conditions (pattern (2), Figure 1) produce the most intense CAT. While patterns (2) and (4) are both associated with upper-level troughs, their orientations result in significant differences in both the locations of CAT and prevalent cloud conditions.

A northeast to southwest-oriented trough axis (pattern (2), Figure 1) results in CAT to the rear of the upper trough in relatively cloud-free conditions. A northwest to southeast trough (pattern (4), Figure 1), which is typically associated with cyclogenesis, results in CAT in advance of the trough, often embedded in thick cirrus clouds. As suggested by Figure 1, sharply curved jet stream segments associated with upper-level troughs or ridges are typically more turbulent than most zonal (predominately westerly) jet streams (see **Dynamical Meteorology: Overview; Inertial Instability; Kelvin–Helmholtz Instability. Synoptic Meteorology: Jet Streaks; Frontogenesis**).

Mesoscale Forcing

Mountain waves

The processes by which gravity waves can produce CAT have been studied extensively for a well-known type of IGW known as a mountain lee wave (typical wavelength: ~ 10 km). Lee waves are generated when stable airflow passes over a topographical barrier. On the lee side of the ridge, the airflow initially descends and then rebounds to generate wave updrafts. As the flow reaches its peak altitude and begins to descend again, a wave crest is

Figure 1 Idealized streamlines at jet stream level showing macroscale flow patterns that are most conducive to the occurrence of CAT. Hatched areas show where CAT is most likely. Lines with arrows represent approximate jet stream locations. The patterns are defined as (1) col or deformation zone, (2) sharp trough, (3) ridge, and (4) negatively tilted trough (associated with baroclinic instability). With (4), the CAT would most likely occur in or near dense cirrus clouds, since this is a favorable flow pattern for cyclogenesis. In day-to-day situations, there are many possible hybrid combinations of these patterns.

formed which may be made evident by the formation of lenticular clouds. Under the crests of strong waves, turbulent rotor circulations are often found in lee wave systems. Occasionally, with large mountain ranges, rotor-produced turbulence will reach the lower altitude range of CAT. In most cases associated with strong turbulence, energy from these waves is trapped at or below a strong temperature inversion near mountaintop level.

In some situations, depending on the wavelength and the distribution of wind velocity and temperature with altitude, lee wave energy can propagate to great heights to produce CAT by one or more of the processes described earlier. Atmospheric conditions typically associated with such higher altitude mountain waves are (1) a high, cold tropopause, (2) a thermal inversion near the mountaintop with (3) weak stability above, (4) low-level winds $>15 \text{ m s}^{-1}$ at mountaintop level, with (5) weak positive vertical wind shear aloft.

The increase of lee wave amplitude with height leads to greater vertical displacement and tilting of the stable layers, and often reduces the local (Ri) enough in local sectors of the wave pattern to produce strong CAT. Furthermore, very strong wave forcing occasionally produces a lee wave 'hydraulic jump' condition, resulting in a deep, extremely turbulent layer in the lee of the mountain, which may extend from near the surface through the tropopause.

An example of an aircraft encounter with severe mountain wave turbulence is shown in [Figure 2](#).

In some cases, a large mountain range will give rise to longer wavelength $\sim 50 \text{ km}$ or more, nearly hydrostatic lee waves. When favorable atmospheric wind and temperature profiles exist, shorter wavelength perturbations induced by these waves may destabilize, owing to partial reflection of lee wave energy from levels near the tropopause. Aircraft flying through such wave action may experience extreme vertical gusts.

Strong cold frontal systems, and jet streams occurring over midlatitude mountainous areas provide conditions favorable for the development of mountain lee waves. The enhancement of CAT-producing mechanisms by mountain waves accounts for the higher frequency of CAT over midlatitude mountains

than elsewhere. However, owing to the set of conditions required for breaking lee waves mentioned earlier, mountain wave-related CAT is not usually found beneath the jet stream core, but mainly on the anticyclonic side (see **Dynamical Meteorology: Overview. Mountain Meteorology: Lee Waves and Mountain Waves**).

Convection-Initiated CAT (CIT)

Another phenomenon that may produce CAT is deep mesoscale convection embedded within moderate to strong winds aloft. If convective cloud elements penetrate a vertically sheared, capping stable layer such as the tropopause, enhancement of those shears will result in the reduction of the local (Ri) and the production of KHI, leading to CIT. In these cases, longer wavelength IGW may also be produced. If stability and wind shear conditions are favorable, then IGW will propagate to their critical levels and break, contributing to CIT as high as several kilometers above the cloud top. Based on numerical model simulations, this latter process may occur even in cases of moderate cloud top winds ($\sim 15 \text{ m s}^{-1}$) and wind shears.

In cases of exceptionally strong convection, tops of thunderstorm cells penetrate the tropopause with vertical velocities as high as $20\text{--}30 \text{ m s}^{-1}$. As a result, IGW develop in the stable stratosphere and propagate away from the thunderstorm, generating CIT. If strong winds are present, flow regimes similar to mountain lee waves develop in the stratosphere, over and downwind of the convection. Therefore, at tropopause levels, an aircraft flying near thunderstorm tops is vulnerable not only to turbulence produced within a thunderstorm but also to CAT outside the thunderstorm. [Figure 3](#) is a record of vertical acceleration and altitude from a commercial jetliner for a CIT encounter near Hannibal, Missouri, on 4 April 1981 that resulted in injuries to passengers.

CAT near thunderstorms in midlatitudes occurs more often during spring and early summer in late afternoon and evening. However, large mesoscale convective systems (MCS) that form

Figure 2 Time history of vertical velocities associated with mountain waves and severe turbulence as measured by an aircraft at 12.4 km (39 000 ft) altitude near Morton, WY, on 16 July 1982. Long-period, relatively smooth mountain waves along the flight path moving upwind (from left to right) deteriorate into extreme CAT conditions associated with KHI closer to the Wind River mountain range ridgeline (near time 210.0 s).

Figure 3 Time history of vertical accelerations (solid) and altitude (dashed) along the flight path of a commercial jet aircraft near Hannibal, MO, from 01.21 to 01.27 UTC on 4 April 1981. The point at which the aircraft flew downwind over the line of thunderstorms is labeled 'Squall Line.'

typically near the axis of an upper-level ridge at night tend to enhance the strength of the jet stream on the poleward side of the MCS. This often results in strong shears and unstable flows, often indicated by transverse cirrus cloud bands, with a significant area of CAT downstream that may continue for several hours after sunrise. Similar conditions may occur on the poleward side of tropical cyclones as they encounter strong westerly winds in the midlatitudes (see **Aviation Meteorology: Aviation Weather Hazards. Numerical Models: Convective Storm Modeling**).

Observations of CAT

Observations of CAT are critical for research, diagnosis, and prognosis of CAT. However, adequate resolution of CAT requires microscale measurements. Such measurements are not regularly available via the standard surface and upper air weather observation networks. Occasionally, instrumented and radar-tracked balloons or ground-based radars have been used for turbulence measurements, but aircraft have been the most frequent platforms of choice for the direct measurement of CAT.

Aircraft Measurements

Subjective pilot reports (PIREPs) include a description of CAT intensity, aircraft position and altitude, and appropriate remarks. Reports of turbulence intensity for most aircrafts are based on the pilot's estimate of flight control difficulty, of the movement of objects within the aircraft, or readings from available instrumentation, for example: (1) airspeed fluctuations, (2) rate of climb in otherwise level flight, and (3) g-meter excursions (see [Table 1](#)). Bias is frequently introduced in these reports as a function of aircraft type, suddenness of onset, and pilot experience, among several factors. Despite these

problems, PIREPs of turbulence are an important day-to-day source of direct CAT measurements.

Improvements in instrumentation and communications have made it possible for automated PIREPs from some commercial airliners to be acquired very quickly by international aviation weather forecast centers, increasing the timeliness and volume of CAT reports.

Some aeronautical and atmospheric research aircrafts are equipped to directly measure true turbulence gust velocities with high accuracy and sample rates (e.g., about 0.3 m s^{-1} and 50 samples per second, respectively). These measurements require specially calibrated sensors, high-capacity data recording systems, and judicious, postflight engineering analysis.

Most commercial airliners carry onboard inertial navigation and digital recording systems that are capable of sampling vertical and horizontal accelerations plus several other parameters including aircraft attitude, engine status, position, and altitude. Such onboard measurement systems provide information for research into the nature and impact of CAT; also, they have laid the foundation for the development of onboard turbulence metrics that lend themselves to automated and standardized CAT reporting, minimizing the bias of subjective CAT reports. Two metrics which suit these requirements are the turbulent kinetic energy (TKE) dissipation rate and the integrated TKE. The latter metric is derived from that part of the TKE spectrum where aircraft have the greatest sensitivity to turbulence. New *in situ* turbulence measurements available from some US airlines provide reports of the cube root of the EDR (see [Table 1](#)) on a 1-min basis.

Beyond using an aircraft as a platform for instruments to measure CAT directly, an ideal airborne CAT detection system should be able to detect the location and intensity of CAT far enough ahead of the aircraft so that the pilot has sufficient time to take evasive flight path deviations and/or to warn cabin crew and passengers to fasten seat belts to minimize the effects of the

turbulence. Although airborne remote sensing of CAT can be achieved partially with forward-looking infrared (IR) radiometers and lidars, the best approach may be the integration of data from multiple detection systems.

Ground-Based Measurements

Although lacking the mobility and limited in number, ground-based systems have generally had the advantage over airborne systems in size, power, and data processing capability to enable the sensing of turbulence and turbulence-related parameters at greater ranges.

Ground-tracked sounding balloon systems, such as radiosondes, are used ordinarily for the determination of indirect turbulence indicators such as stability, wind velocity, wind shear, and (Ri). An ongoing problem with the twice daily (00.00 coordinated universal time (UTC) and 12.00 UTC) radiosonde observations is the poor detection of thin, potentially turbulent layers, which may vary rapidly in time and space. A few specialized sounding balloon systems, such as those used for the support of the launch of space vehicles (e.g., radar tracking of the rigid, Jimsphere balloons at Cape Canaveral), are capable of resolving layers of 50 m or less. Some studies have used balloon rate-of-rise fluctuations to find a direct correlation between large-amplitude IGW vertical motions and turbulence in CAT regions.

Sensitive, vertically pointing, scanning Doppler radars, known as wind profilers, are used to acquire time sequences of wind speed and direction as a function of altitude. Ultra high frequency (UHF) or very high frequency (VHF) wind profilers are capable of making a complete sounding every 30–60 s with samples at 250 m intervals over an altitude range of 0.5–16 km above ground level (AGL). Typically averaged over a period of an hour to eliminate noise, profiler data are most useful for determining the altitude, intensity, and temporal behavior of larger scale features associated with CAT, such as shear zones, trough lines, and jet streams.

Very powerful ground-based research radars are capable of detecting clear air echoes associated with KHI. Modern Doppler weather radar systems can measure turbulence in clear air, based on the variance (or 'spread') of the velocity distribution, although that capability is generally limited to the boundary layer. Most operational Doppler radar systems may also be used to determine higher altitude wind information similar to that from wind profilers.

Ground-based research light detection and ranging (lidar) has been used to accurately measure wind profiles and observe violent wave-breaking episodes at jet stream altitudes. However, such observations cannot be acquired under all sky conditions; this is because the air at the turbulence locations must have enough particles to reflect some of the lidar energy, and the intervening path between the lidar and the turbulence must not have so many particulates or droplets that these would block the lidar beam or its return signal.

Remote Sensing from Space

The advent of the geostationary meteorological satellites in the later half of the twentieth century provided an additional tool for monitoring regions of potential turbulence. Although pixel

resolutions are only marginal for this purpose (1–5 km), the image frequency (5 min–1 h) and spatial coverage (global except near the poles) of geostationary satellites can be quite useful for the detection and short-range forecasting of CAT, especially when combined with other data. Spectral bands most useful for CAT detection are visible, IR, and water vapor (WV) (Table 2). Specific applications of these images will be described in more detail in the next section. Cloud motion vectors derived from a sequence of geostationary satellite images can provide valuable data over remote data-sparse regions for assimilation into numerical prediction models.

Visible and IR images from polar orbiting satellites are available less frequently (every 2–6 h, depending on latitude), but can be used to identify CAT cloud patterns associated with long-lasting, large-scale systems, and to corroborate features observed in geostationary satellite data. They are especially useful at high latitudes where geostationary coverage is poor because of extreme parallax.

Analysis of satellite imagery, compared with colocated PIREPs, indicates that CAT is found not only in clear air but also in cirrus clouds, and along borders of large-scale convective cloud systems. Zones of turbulence associated with the subtropical jet stream and convective outflow are often denoted by pronounced cirrus cloud bands that are oriented nearly perpendicular (transverse) to the flow. These clouds bands are possibly caused by shallow convection, similar to horizontal convective rolls in the boundary layer, and/or by other processes such as gravity waves or inertial instability. An example of this cloud feature associated with a subtropical jet is shown by the Geostationary Operational Environmental Satellite (GOES) IR image in Figure 4. Wider, thicker transverse cloud bands have been associated with a strong likelihood of moderate to severe CAT.

WV images from geostationary satellites are sensitive to moisture in the middle and upper levels of the troposphere. Pronounced warming (drying) observed over a period of a few hours in a series of WV images has been associated with strong subsidence and tropopause 'folds' in the vicinity of upper-level fronts, and a corresponding increase in the risk of CAT. These regions are usually associated with horizontal deformation zones (pattern (1), Figure 1), sharp upper troughs (pattern (2), Figure 1), or in the 'dry slot' region of intensifying cyclones. These synoptic patterns also correlate with high concentrations of stratospheric ozone and large values of potential vorticity. Objective methods are being developed to identify tropopause folds automatically using 6.7 μm WV imagery.

Table 2 Spectral channels used in detecting CAT-related phenomena from space

Channel type	Spectral range (μm)	Applications
Visible	0.5–1.0	Small-scale (≤ 1 km) wave clouds
IR	10–12	Cloud top temperatures (heights), mesoscale (up to 10^3 km) cloud borders, cloud bands, and wave clouds
WV	6–7	Regions (10 – 10^3 km) of sinking/rising associated with mountain waves, upper-level fronts, deformation zones, and cyclones

Figure 4 IR image from the GOES-8 at 00.45 UTC on 3 March 2000, showing transverse cirrus cloud bands on the equatorward side of the subtropical jet stream near the Leeward Islands. Moderate-to-severe turbulence was reported by a B767 aircraft at the location shown. Wind barbs are from radiosonde sites for 250 hPa at 00.00 UTC, or aircraft reports for 8.9–11.8 km (28 000–37 000 ft) between 00.00 and 03.00 UTC.

Satellite images in several spectral bands (visible, IR, and WV) may also show classic ‘washboard’ cloud patterns associated with mountain waves (Figure 5). The WV images often depict a greater area coverage of mountain wave conditions than either visible or IR, owing to their greater sensitivity to moisture. Warm subsidence zones oriented along and just downstream from the mountain ridges and slightly upstream from the lee cirrus plume, sometimes referred to as ‘Föhn gaps,’ are indicative of possible intense turbulence at high altitudes (upper left of panel a in Figure 5).

High-resolution visible imagery (0.5–1 μm) can sometimes detect very small-scale (≤ 1 km wavelength) wave cloud patterns (referred to as ‘billows’) that correspond to areas of KHI. Billow clouds are embedded typically within or near large-scale cloud systems, or in the vicinity of convective storms when wind shears are present (see **Satellites and Satellite Remote Sensing: Temperature Soundings; Surface Wind and Stress**).

CAT Prediction Techniques

As illustrated in Figure 1, certain synoptic-scale upper flow patterns have been empirically related to CAT occurrence through many years of operational experience. By applying these pattern types to predicted flow patterns from numerical forecast models, estimates can be made of the likelihood of CAT in certain regions for longer forecast time periods.

Objective prediction of CAT has become more commonplace and accurate, owing to increased computing speed, diminished cost of high-speed computers, improved numerical model physics, and better techniques for assimilation of wind and temperature data from aircraft and satellites into the numerical models.

A number of diagnostic and predictive indices for CAT have been developed and used over the years. The nondimensional (Ri) (see eqn [1]) is adequate in many situations, although it often exhibits a much wider range of critical values

Figure 5 Mountain wave patterns east of the Rocky Mountains observed by GOES-8 in the (a) WV, (b) IR, and (c) visible band at 19.15 UTC on 5 April 2000. Considerable severe turbulence was reported below 6.4 km (20 000 ft). The WV image depicts more extensive coverage of mountain waves than the other two images. Cirrus plumes observed in upper left are indicative of high-altitude mountain waves downwind of the Salt River and Wind River ranges in Wyoming.

in the free atmosphere than in the laboratory. (Ri) is most reliable when generated from high-resolution observational data; therefore, it is principally used as a diagnostic tool. (Ri) is defined as:

$$(Ri) = \frac{(g/\theta)(\partial\theta/\partial z)}{(\partial V/\partial z)^2} \quad [1]$$

where θ is the potential temperature (K), V the vector horizontal wind (m s^{-1}), g the acceleration of gravity (m s^{-2}), and z the height (m).

A more successful index for CAT prediction employs the (Ri) tendency equation. Significant, prolonged turbulence is most likely in regions of the atmosphere where larger scale processes are continually acting to decrease (Ri) , despite the influence of turbulent mixing. The primary processes include horizontal deformation, convergence, and differential thermal advection. Specifically, the (Ri) tendency technique calculates the large-scale forcing necessary to overcome the kinetic energy dissipation resulting from the turbulence process in order to maintain the (Ri) at values $\leq 1/4$. A simple formulation of (Ri) tendency equation is

$$\frac{d\ln(Ri)}{dt} = -\Phi - \varepsilon \quad [2]$$

where Φ is the nonturbulent, large-scale forcing by deformation and ε is the turbulent dissipation.

A similar approach can generate a diagnostic or predictive index by simply calculating the product of horizontal, resultant deformation, and the vertical vector wind shear at each grid point. The basis of this index is similar to (Ri) tendency in that it considers large-scale forcing from frontogenesis, in addition to the presence of vertical shear in the mesoscale. One difficulty with this approach is that deformation can also lead to frontolysis in some cases, which tends to reduce vertical shear. This turbulence index (TI) is defined as:

$$TI = \frac{[(\partial u/\partial x - \partial v/\partial y)^2 + (\partial v/\partial x + \partial u/\partial y)^2]^{1/2}}{\text{Resultant deformation} \times \partial V/\partial z} \quad [3]$$

Vertical shear

where u and v are wind components (m s^{-1}), V the vector wind, and z the height (m). A recent improvement to TI incorporates temporal changes in divergence that captures a wider range of CAT events, with a minimal cost in overprediction.

The TKE technique for the prediction of CAT attempts to show areas of turbulence generation through the processes of production by vertical shear, production or destruction by buoyancy, energy advection, and loss via dissipation. The simplified TKE equation can be expressed as:

$$\frac{d(\text{TKE})}{dt} = \underbrace{-u'w'\frac{\partial u}{\partial z} - v'w'\frac{\partial v}{\partial z} + w'\theta\frac{\varepsilon}{\theta}}_{\text{Energy production Shear production Buoyancy} + A - \varepsilon} \quad [4]$$

Advection Energy dissipation

where $\text{TKE} = (u'^2 + v'^2 + w'^2)/2$, total kinetic energy per unit mass, u' , v' , and w' are perturbation (gust) velocities, and A is an advection term.

The TKE approach can account for turbulence from a wide variety of mechanisms such as convection and mountain

waves, as well as jet stream CAT, and provides a direct estimate of possible turbulence intensity through the energy dissipation rate. While TKE presents the most rigorous depiction of turbulent processes of all the objective approaches, it is more effective when numerical models have very high vertical (~ 100 m) and horizontal resolutions (~ 10 km). In solving eqn [4] using such high-resolution models, the need for accurate observations is critical, and the best analysis and prediction results are attained in regions of dense reporting networks that incorporate aircraft data, chiefly over continental areas.

The indices described above do a reasonably good job of predicting large outbreaks of CAT, but tend to predict CAT over a region that is larger than the area of actual occurrence (also known as 'overprediction'). Their inadequacies are due largely to the following factors: (1) they only account for large-scale conditions favorable for CAT, (2) they do not consider triggering mechanisms, and (3) most numerical models cannot accurately account for the intense, subgrid-scale vertical shears and strong horizontal forcing present during severe CAT. More specifically, model problems are due to resolution limitations and systematic underforecasting of maximum wind speeds within the jet stream.

A new direction in CAT forecasting that is based on a specific triggering mechanism employs the Lighthill–Ford (LF) theory of spontaneous generation of gravity waves. Scaled for midlatitude synoptic-scale flows, it can be expressed to second-order accuracy as a shallow water wave equation for inertia–gravity waves with the following wave forcing terms:

$$LF \sim f\mathbf{u} \cdot \nabla \zeta - \frac{\partial}{\partial t} J(u, v) + 2Df\zeta + f\left(v\frac{\partial D}{\partial x} - u\frac{\partial D}{\partial y}\right) \quad [5]$$

in which f is the Coriolis parameter, ζ is the relative vorticity, and D is the horizontal divergence.

Initial experimental results with this index coupled to a first-order TKE closure technique have indicated a high degree of skill, particularly for moderate or greater CAT. While differences exist regarding the applicability to CAT occurrences and its operational implementation, this new approach has the potential to significantly improve CAT forecasting (see **Gravity Waves: Overview. Turbulence and Mixing: Overview; Turbulence, Two Dimensional; Turbulent Diffusion**).

Statistical Approaches to CAT Prediction

Because of the sporadic, microscale nature of CAT, it would seem that statistical approaches would be useful for forecasting its occurrence. The first such efforts were completed in the United Kingdom in the late 1970s. Turbulence data from about 4500 aircraft reports, compared with 11 colocated numerical parameters derived from a coarse-resolution prediction model, revealed that the best correlation was between CAT and vertical and horizontal wind shears. Similar studies were completed in the United States in the 1980s using higher-resolution numerical model data that showed CAT to be highly correlated with horizontal deformation and scalar wind speed.

A technique that statistically integrates information from many numerical turbulence indices, known as the Graphical Turbulence Guidance (GTG), was developed in the late 1990s, initially for use over North America. GTG first assigns a score to

each diagnostic index, based on comparison with available PIREPs at the initial time period throughout the numerical grid domain. A weighted sum is then determined from all of the indices to arrive at a final GTG index value at each grid point. The same weights are then assigned to each index in deriving predictions for each forecast time period. This process (known as 'dynamic weighting') is repeated with every forecast cycle. GTG algorithms have been developed for both upper level (above 6.1 km (20 000 ft)) and mid-level (3.0–6.1 km (10 000–20 000 ft)). Ten indices are used for the upper level, while nine are applied for mid-level forecasts. The mid-level GTG uses some of the same diagnostic indices as the upper level, but with a few that are different. GTG is also under evaluation for use in other regions of the globe, such as East Asia.

To be successful, an objective TI must provide high probability of detection for turbulence (POD_y), coupled with an acceptably low false alarm rate (FAR). The POD for smooth conditions (POD_n) is preferred over FAR in turbulence and icing verification because POD_n is less sensitive to the number of PIREPs in the data sample than FAR. A metric often used in CAT forecast verification that combines POD_y and POD_n is the True Skill Statistic ($TSS = POD_y - POD_n - 1$).

A verification method that has gained favor is the relative operating characteristic (ROC), derived from signal detection theory. In an ROC graph (such as shown in Figure 6), the performance of CAT forecasts for various thresholds of a given index is plotted in terms of $1 - POD_n$ (x-axis) and POD_y (y-axis). The metric $1 - POD_n$ can be interpreted as the proportion of smooth reports that are incorrectly classified. This creates a curve that traces out the index's performance for all choices of values that trigger a 'yes' forecast for turbulence, from high thresholds (low POD_y , low $1 - POD_n$) to low thresholds (high POD_y , high $1 - POD_n$). The area under the ROC curve is a quantitative estimate of skill; values greater than 0.5 indicate that an index's performance is better than sheer chance.

The GTG procedure minimizes forecast errors due to uncertainties in individual turbulence diagnostic indices and their

respective thresholds. Verification using PIREPs has shown that GTG output based on the dynamic weighting system described above is generally superior to the individual indices based on POD_y , POD_n , TSS, and ROC statistics (Figure 6). The LF method, which is still under evaluation, has shown the potential to provide even better skill in ROC statistics.

Although useful, statistical approaches to CAT prediction are not always able to correctly depict turbulence events accurately because of limitations in numerical model data or scarcity of PIREPs at the initial time period. Climatologically determined weights developed for GTG hold some promise for use in data-sparse regions. The best results for CAT prediction in the long term will likely stem from the development and improvement of physically based techniques, such as LF, that are then incorporated into increasingly sophisticated statistical schemes.

CAT Climatology Studies

Some advances in the knowledge of the global distribution of CAT along heavily traveled airways have been derived from programs that collected large numbers of PIREPs, such as one conducted by the International Civil Aviation Organization in the mid-1960s. With the rapid increase in high-altitude flights since then, PIREP-based CAT climatology studies have become more meaningful, although they still lack sufficient data in many regions. For example, a recent study over the United States based on more than two million PIREPs over a 12-year period found that regional maxima in CAT frequency occur over the central Rocky Mountains, the South, Southeast, and along the North Atlantic seaboard. However, there were some large regions in the southwest near the Mexico border that had very little data, probably due to flight restrictions over military operation areas.

The improvement of numerical prediction models over the past several decades has resulted in their viable use in global CAT climatology studies. More comprehensive global 'climatologies' of large-scale, upper-level conditions favorable for CAT have been constructed by averaging numerical model indices (such as the TI described in CAT Prediction Techniques) to infer the global distribution of CAT activity. This approach usually describes CAT produced by jet streams and upper fronts (e.g., cyclogenesis), but does not account for mountain waves and convection. It also does not provide an indication of the likelihood of severe turbulence.

Based on a 44-year average of TI for example, regions of relatively high CAT risk have been identified over Southern and Eastern Asia, Southwestern and Central United States, and coastal Northeast United States and Canada (Figure 7). A short period (2 years) study using TI in the Southern Hemisphere, which has relatively little land mass, has indicated that maximum CAT is likely near Southern Australia and New Zealand (not shown).

The seasonal variation of the mean TI (Figure 7) also shows that the zone of maximum CAT occurrence tends to weaken and shift poleward during the warm season in each hemisphere (Figure 7), as one would expect due to the annual migration and weakening of the jet stream and upper-level fronts.

Large year-to-year changes have also been observed in these data that are likely related to interannual oscillations, such as the

Figure 6 ROC curves of the performance of 6-h forecasts of the upper-level version of GTG for 2003, validated using nearly 50 000 PIREPs. Individual CAT diagnostics are shown in thin gray lines; the GTG combination is the heavy, solid curved line; and the dot represents the average performance of Airman's Meteorological Information (AIRMETs) (with amendments). The thin diagonal line through the origin represents the no-skill line. Reproduced from Sharman, R., Tebaldi, C., Wiener, G., Wolff, J., 2006. An integrated approach to mid- and upper-level turbulence forecasting. *Weather and Forecasting* 21, 268–287.

Figure 7 Mean frequency (%) of high values ($>12 \times 10^{-7} \text{ s}^{-2}$) of the CAT TI (shaded areas) for the Northern Hemisphere winter (a) (Dec., Jan., and Feb.) and summer (b) (Jun., Jul., Aug.) based on 44 years of data (1958–2001). Contours show mean wind speed (m s^{-1}). The index was derived from the European Center for Medium Range Weather Forecasts (ECMWF) reanalysis data set (ERA40). Turbulence is likely to be underestimated, since the index does not account for mountain waves or deep convection. Reproduced from Jaeger, E.B., Sprenger, M., 2007. A Northern Hemispheric climatology of indices for clear air turbulence in the tropopause region derived from ERA40 reanalysis data. *Journal of Geophysical Research* 112, D20106, doi:10.1029/2006JD008189.

El Niño Southern Oscillation (ENSO) phenomenon. During strong El Niño conditions, the subtropical jet stream in the Northern Hemisphere is typically much stronger than normal, resulting in a higher potential for CAT occurrence in regions where it converges with the polar jet stream (such as over North Africa and the Southwest United States).

Introduction

The sulfur cycle transfers enormous amounts of this biologically important element through the atmosphere every year. Despite the size of natural reservoirs, human activities have had a remarkable effect on the sulfur cycle, perhaps most notably in the production of acid rain. The Earth's surface is a source of windblown dusts, but this is influenced by grazing activities and desertification. Large amounts of sulfur are mobilized by mineral extraction and fuel use. Fossil fuel refining and combustion are the major human emissions to the atmosphere, which exceed the natural sources. The reduction in anthropogenic emissions from North America and Europe is countered by growing emissions from Asia and may represent a special challenge for the twenty-first century.

Sulfur

The sulfur cycle is one of the major elemental cycles. Sulfur has an enormous span of oxidation states: from sulfides in the $-II$ state through to sulfates in the $+VI$ state. Both sulfides and sulfates are frequently found as minerals, which include the innumerable sulfides of metals or sulfates such as that of calcium (gypsum) and/or barium (barite). Sulfur is also found in its elemental state. Rhombic and monoclinic crystalline forms both contain S_8 rings. Liquid sulfur undergoes sharp changes in properties (color, viscosity, specific heat) as the temperature rises above the melting point (112.8°C for rhombic sulfur), with complex changes in the ring structure. Sulfur is essential to living organisms because it is incorporated into amino acids, proteins, and other biomolecules.

There is a naturally occurring radioisotope, sulfur-35, produced by the interaction of cosmic rays with argon in the upper atmosphere. It has a radiochemical half-life of 87 days and is rapidly oxidized to sulfur dioxide (SO_2) and sulfate, which is ultimately transferred to the lower atmosphere and removed in rain.

Evolution of the Sulfur Cycle

Sulfur is a common element with a high cosmic abundance half that of silicon (a frequent marker element). Concentrations of sulfur are much reduced in the Earth's crust because of downward separation when it is segregated in heavy sulfide magmas. Places where sulfur is plentiful are usually the result of intrusions that occurred in the earliest stages of the Earth's history. The element remains very much associated with volcanic activity. The Earth formed through gradual accretion of infalling material during Hadean time (4.5 to 3.8 billion years ago). Accretion left the mantle extensively molten. Gradually the Earth's surface cooled and solid rock formed, probably prior to 3.8 billion years ago. Metallic iron influenced the oxidation state of outgassed volatiles and hydrogen sulfide would have made an important contribution to the early sulfur budget. This differs from the current dominance of volcanic gases by sulfur dioxide. On the Archean Earth (3.8 to 2.5 billion years ago) hydrogen sulfide could be removed from the atmosphere through dissolution and precipitation as iron sulfide from the oceans or destruction by photochemical processes or lightning in the atmosphere.

Within the early oceans the concentration of sulfate would have been controlled by the provision of oxidizing materials from the atmosphere. Sulfate could not have risen to high

concentrations, while the hydrogen content of the atmosphere was maintained in excess of 0.0001 atm through rapid volcanic input.

Atmospheric oxygen remained considerably less abundant through the Archean (3.4 to 2.8 billion years ago) than today. Nevertheless at the beginning of the Archean, anaerobic photosynthesis provided a weak source of sulfate to the global ocean. Photodissociation of water provided a limited amount of oxygen that was supplemented with oxygen from oxygenic photosynthesis about 2.8 billion years ago. This would probably lead to atmospheric oxygen concentrations high enough to oxidize the sulfur in pyrite to sulfate. Bacterial reduction of sulfate to sulfides in marine sediments is a good indicator of increasing sulfate in sea water, with early indications found between 2.7 and 2.5 billion years ago. The sedimentary sulfur isotope record suggests that there were low concentrations of seawater sulfate and oxygen in the early Archean and atmosphere, respectively. Sulfate concentrations in sea water were probably less than a millimolar until the substantial oxygen increases of the early Proterozoic (2.5 to 0.54 billion years ago).

Volcanic Sources of Sulfur

Although elemental sulfur occurs in volcanic gas, perhaps as the dimer, most is found as either SO_2 or hydrogen sulfide (H_2S). The equilibrium calculations of the composition of volcanic gases show oxidized systems that contain SO_2 , and smaller amounts of S_2 and H_2S . More reduced systems may have COS and H_2S in greater relative abundance.

Some fluxes of sulfur gases from volcanoes occur as fairly continuous small releases from fumaroles into the atmospheric boundary layer. Violent volcanic eruptions represent a more sporadic but potentially much larger source of sulfur. The Tambora eruption of 1815 released some 50 Tg of sulfur, but this was exceptionally large (by comparison the Pinatubo eruption of 1991 released perhaps only one-fifth as

much). Such explosive volcanism can inject materials into the atmosphere with such force that the sulfur compounds can be driven into the stratosphere (Figure 1 and Figure 2). These gases are slowly converted to sulfate aerosols with a residence time of about a year in the stratosphere. Larger ash particles sediment out more quickly. Sulfur condenses as sulfur crystals on rocks near volcanic vents. This has provided a source of sulfur since ancient times and the risky activity of mining volcanoes for sulfur continues to the present day.

The variability and the shifting balance between fumarolic and explosive injections make globally averaged emission estimates difficult. Over the last quarter of the twentieth century the annual volcanic emissions have varied by a factor of three, but on average they were 7 Tg(S) year⁻¹ as SO₂ and about 2.6 Tg(S) year⁻¹ as H₂S. The volcanic emissions of carbon disulfide and carbonyl sulfide are an order of magnitude lower than H₂S.

Recently it is clear that the sulfuric acid droplets in the stratosphere (Figure 2) can enhance ozone depletion by providing sites for heterogeneous reactions. This can lead to a reduction in the thickness of the ozone layer after volcanic eruptions.

Marine Sulfur Sources

Present-day sea water has very high concentrations of sulfur, largely because of its high solubility as the sulfate. Sulfate is found at 0.028 mol l^{-1} and is thus the most abundant anion apart from chloride. Hydrothermal processes at midocean ridges are able to reduce sulfates to sulfides. As sea water evaporates it first precipitates calcium and magnesium carbonates, and calcium sulfate, gypsum. When sea water is trapped within basins in arid climates, it can lead to extensive deposits of evaporite minerals. In the geological past these shallow basins were more extensive than at present and gave rise to very extensive evaporite beds.

Sea spray can be blown directly from the sea surface during high winds. The particles of salt from this process tend to be

Figure 1 Atmospheric sulfur cycle with fluxes in Tg(S) year^{-1} . The reduced sulfur compounds DMS, OCS, and CS_2 come largely from marine processes. In years with much explosive volcanism there can be large sources of SO_2 directly to the stratosphere. Adapted with permission from Rodhe (1999).

Figure 2 Vertical profile of sulfur species. The sulfate aerosol layer in the stratosphere has important effects on temperatures and ozone depletion. The marine and continental profiles for sulfur dioxide are different in the troposphere.

large and short-lived. Smaller particles are produced during bubble bursting. The very finest arise when the cap of a surfacing bubble shatters, giving film drops that dry into salt crystals of 5–50 pg. Along with these are larger jet drops that emerge as the bubble cavity collapses and give particles of about 0.15 μg . Such processes lead to the production of around a gigagram of sea salt particles each year, of which 30 Tg would be sulfur in the form of sulfate. Thus high chloride and sulfate concentrations are found in coastal rainwater.

H_2S is extensively produced from sulfate reduction in tidal flats and marshes. This is not surprising given the high concentration of sulfate in sea water. H_2S had long been associated with biological activities and was always assumed to be an important source of reduced sulfur to the atmosphere. Anaerobic environments are protected from invasion of oxygen through burial or lying underwater. This limited exchange of oxygen can also restrict the loss of biogenic H_2S to the atmosphere. Concentrations are typically in the range 30–100 ppt in remote air, although on tidal mud flats or in volcanic regions they can be much higher. H_2S oxidizes rapidly in sea water (c. 10 min), so any of this gas found in marine air would have to be produced close to the sea surface.

A preoccupation with H_2S has meant that early studies overlooked other reduced sulfur gases. The most notable was dimethylsulfide (DMS or CH_3SCH_3) identified first by James Lovelock in the 1970s. DMS is the largest natural source of reduced sulfur gases. It is produced through the activities of phytoplankton and most arises from dimethylsulfonium propionate ($[(\text{CH}_3)_2\text{S}^+\text{CH}_2\text{CH}_2\text{COO}^-]$ or DMSP) which leaks from aging or ruptured cells. The bacterial decomposition of DMSP in sea water cleaves it into DMS and acrylic acid:

High concentrations of DMS are found in areas where micro-organisms are abundant, but the amounts released vary with

species and the stage of their life cycle. Seasonal maps of DMS in sea water in the oceans have become quite detailed, reflecting its biological origin. DMS is released from sea water as it is relatively insoluble and readily transfers to the atmosphere. The fluxes to the atmosphere are dependent not only on concentration but also on wind speed. However, there remains an uncertainty of a factor of two with the estimated emissions of 20 Tg(S) year^{-1} . Some DMS in sea water is oxidized, probably to dimethylsulfoxide (DMSO, CH_3SOCH_3). This may be a photosensitized or biological oxidation, while some DMSO is produced directly from biological activities.

DMSO is more soluble than DMS, and so is unlikely to degas from sea water in large amounts. Other alkyl sulfides are more likely to be released from the ocean, but their abundances and thus fluxes are much smaller. Methanethiol (CH_3SH) and dimethyldisulfide (CH_3SSCH_3) are perhaps the best known of these.

The oceans are also a source of carbon disulfide (CS_2) which is released from the ocean at about 0.2 Tg year^{-1} . CS_2 is produced by photosensitized reactions in sea water. Laboratory irradiations have confirmed that the amino acids cysteine and cystine are efficient precursors of CS_2 . Biological production of CS_2 has also been observed in some marine phytoplankton.

CS_2 can be easily oxidized and contributes to the production of carbonyl sulfide (OCS). There are also photochemical mechanisms for the production of OCS from organic matter in the oceans. The emissions show a diurnal cycle due to the photochemical origin, but the fluxes from the ocean are much smaller than DMS. Nevertheless OCS is the most abundant reduced sulfur gas in the atmosphere as it is very stable in the troposphere (25 year residence time) and thus able to build up to substantial concentrations (0.5 ppb).

The low-temperature oxidation products of atmospheric DMS, most notably DMSO, dimethylsulfone ($\text{CH}_3\text{SO}_2\text{CH}_3$), and methanesulfonic acid (MSA, $\text{CH}_3\text{SO}_3\text{H}$), have been found in the Antarctic atmosphere typically at 1.5, 1.3, and 30 ppt, respectively. They may all be found in rainwater, but MSA is especially soluble and so is largely associated with aerosol particles. At times MSA is almost as abundant as non sea salt sulfate (NSS), but under warmer conditions it may only be a 50th that of NSS, the major oxidation product.

These marine sources of reduced sulfur gases can be important as a source of sulfur to the continents. The gypsum accumulations of the hyper-arid Central Namib Desert derive from non sea salt sulfur, in particular oxidation products of marine DMS.

Terrestrial Sulfur Sources

Windblown dusts are important as a source of sulfate in the atmosphere. The largest of these often occur from evaporitic deposits. Dusts from the margins of the Aral Sea (0.1–1 Tg year^{-1}) and arid states of the southern United States are notable source regions.

Biogenic sulfur emissions from land have also been recognized as making an important contribution to the global budget, but the fluxes have been more difficult to establish. Many of the gases that originate from biological activity in the

Oceans are also emitted from the continents, although the quantities are far less certain. Growing crops and biochemical activities in wetlands, especially in salty coastal environments, give predominantly DMS, H₂S, and methyl sulfide, with generally much lower amounts of OCS and CS₂. Tundra, while seemingly a likely source, has been found to be a low emitter of reduced sulfur because of low sulfate amounts in the water.

Biological Sinks for Sulfur

Vegetation can remove sulfur compounds from the atmosphere. Carbonyl sulfide removal by plants is the best known and probably represents a dominant sink for tropospheric OCS. The fate of some oxidation products of DMS is not clear. Some biochemical studies suggest that they may degrade biologically. Facultatively methylotrophic species of *Hyphomicrobium* and *Arthrobacter* seem to be able to produce enzymes necessary for a reductive/oxidative pathway for DMSO and dimethylsulfone (although the former appears to be more generally utilizable). Methanesulfonic acid is stable to photochemical decomposition in the atmosphere and its fate on land has been puzzling. A range of terrestrial methylotrophic bacteria that appear common in soils may mineralize MSA to carbon dioxide and sulfate.

Anthropogenic Sulfur Sources

The most pernicious source of human sulfur emissions has been from the combustion of high-sulfur coals. This began in thirteenth-century London with the depletion of nearby wood supplies and increased through the centuries that followed until it reached its peak within the early twentieth century in Europe and North America. In Asia, particularly, emissions have continued to grow with the enormous pressure of industrial development. In the North Atlantic sector there has been a general decline in sulfur emissions with a shift away from coal as a fuel, in all but extremely large industrial plants, as a response to the problems of urban air pollution and acid deposition. It is estimated that in south and eastern Asia more than 10⁷ km² of land will be subjected to sulfur deposition greater than 1 g(S) m⁻² year⁻¹ by AD 2020.

Sulfur in coal exists half as pyrites, which is relatively easy to remove, but the rest is organically bound. This makes it hard to remove except by methods such as coal gasification or in stacks after emission. Sulfur can be removed by catalytic hydrodesulfurization from residual oil, but it leads to fuels that tend to become waxy at low temperature.

The combustion of fuels leads to the release of SO₂ in a simple but effective oxidation:

Many refining and extractive processes release large amounts of air pollution containing SO₂. For example, sulfide ores have been roasted in the past with uncontrolled emissions:

The SO₂ released often destroyed large tracts of vegetation downwind from smelters.

Various techniques are used to remove sulfur from stack gases. The use of lime (calcium hydroxide) or limestone (calcium carbonate) slurries to absorb SO₂ is widely adopted. The main product, calcium sulfate, is not seen as an environmentally hazardous by-product, although it can be contaminated with trace metals. However, the amounts of lime required can be extremely large. There are often problems where these are mined from attractive sites of great ecological and recreational value. Regenerative desulfurization processes such as the Wellman-Lord procedure absorb SO₂ into sodium sulfite solutions converting them to sodium bisulfite. The SO₂ is later degassed and can be used as a feedstock for the chemical industry (i.e., the production of sulfuric acid).

Catalytic converters in vehicles have been used to remove nitrogen oxides, carbon monoxide, and hydrocarbons from exhaust streams. However, under fuel-rich driving cycles (i.e., lots of accelerating and decelerating), hydrogen gas is produced in the exhaust. Three-way catalysts contain cerium dioxide, which stores sulfur from gasoline under driving conditions as cerium sulfate. Reduction of the cerium sulfate by hydrogen gas allows the formation of H₂S. This can create a noticeable odor, where traffic is heavy.

Atmospheric Sulfur Chemistry

Typically the gases we have been discussing are in a somewhat reduced form in the atmosphere and undergo oxidation. DMS is oxidized in an oxygen-rich atmosphere via OH attack:

DMSO can yield dimethylsulfone. Methanesulfonic acid is an important product of DMS oxidation although the process is not entirely clear. It has been suggested that this arises from CH₃SO₂ produced in a sequence of reactions that follow hydrogen abstraction by OH from DMS. Once fragmented, the S from DMS can oxidize to SO₂ and sulfuric acid. Lower temperatures as found at high latitude appear to favor the production of larger proportions of DMSO and MSA rather than the more complete oxidation through to SO₂. The oxidation of DMS typically takes place at time scales of about a day. These processes are an important source of sulfuric acid over the ocean and contribute to the production of cloud condensation nuclei. Sulfur in this form is usually called non sea salt sulfate to distinguish it from the sulfate from sea salt.

CS₂ reacts in the atmosphere with a 7 day residence time.

OCS oxidizes only slowly:

However, in the stratosphere the molecule can photofragment into CO and S which can ultimately oxidize to contribute to sulfate particles.

Homogeneous oxidation of SO_2 takes place through OH attack:

The sulfur trioxide reacts very rapidly with water to form sulfuric acid. This can be a significant pathway, but if liquid water is present heterogeneous mechanisms yield most of the sulfate.

Chemistry of Sulfur in Rain and Cloud Water

The interaction of SO_2 with water is responsible for much of its removal from the atmosphere. SO_2 is not especially soluble in water, but subsequent equilibria increase the partition into cloud water at typical pH values.

where m and p refer to the molarity and pressure of aqueous and gaseous species, respectively.

SO_2 dissolves in water as $(\text{SO}_2)_{\text{aq}}$ 'sulfurous acid' (H_2SO_3). It is usually sufficient to treat only the first dissociation to the bisulfite anion (HSO_3^-) as the subsequent dissociation to the sulfite ion is usually small in cloud droplets. The concentrations expressed here in molar or molal units should be as activities, but in rainwater the deviations from ideality are small. At pH 5.4 in a typical cloud with a gram of liquid water in each cubic meter, SO_2 will partition equally into both phases. Once dissolved, sulfur dioxide can be oxidized, but oxidation by dissolved oxygen is typically rather slow. The production of sulfuric acid, which is much stronger, leads to acidification.

This simple oxidation can be catalyzed by iron, manganese, and other transition metals in the atmosphere, but in unpolluted rainfall the metal concentrations are likely to be low. Here more typically the reaction proceeds with oxidants such as dissolved hydrogen peroxide (or other atmospheric peroxides) and ozone. The hydrogen peroxide route is a particularly significant one as the reaction is faster in acid solution. This means that it does not slow as the system becomes more acidic with the production of sulfuric acid. This oxidation can be represented as follows:

Hydrogen peroxide is an especially important droplet phase oxidant because the gas is very soluble in water and readily produced in atmospheric solutions by photochemical mechanisms. Other oxidants produced in solution, such as peroxynitric acid, appear to be important:

The ozone-driven oxidation is written as

and although ozone is abundant in the atmosphere it is not very soluble.

In general, the overall oxidation in the remote atmosphere takes 2–4 days, but under some conditions it can be much faster. In urban areas plentiful supplies of transition metal catalysts and oxidants can enhance the rates considerably, especially if there are alkaline materials from fly ash or ammonia to neutralize the growing acidity of droplet phases which limits SO_2 solubility.

Land surfaces, particularly those covered by vegetation, represent a further removal process as SO_2 is dry deposited to these surfaces. Although we use the term dry deposition, the vegetated surfaces act as if they are wet and gas exchange takes place with effectively wet surfaces on or inside leaves. Such dry deposition is most significant where SO_2 concentrations are high (polluted regions). The dissolution of SO_2 in water, most particularly sea water (which is alkaline), represents a further important sink.

Acidification

The production of sulfuric acid in air masses over industrialized continents led to the acid rain problem. This acidification was recognized by the mid-nineteenth century, initially as emissions of hydrochloric acid from the alkali and soap industry, but later coal combustion was also seen as an important source of acid. By the 1950s, long-term records of rainfall chemistry showed increasing fluxes of sulfuric acid to the ground. In Scandinavia, poorly buffered soils began to respond to the effects of acid rain and the pH of lakes declined, resulting in a loss of fish. Through the 1970s and more particularly the 1980s, acid rain became a keenly fought environmental issue, which led to a range of protocols in North America and Europe that served to limit the release of sulfur into the atmosphere.

Acids accumulated over the winter are concentrated into the first meltwaters of spring and send an acid shock through the environment. Young fish are readily injured, but amphibians such as frogs and salamanders also suffer. More generally the delicate ecological web that depends on the freshwater systems is affected. The debate over acid rain also examined the effects on forests. Forest damage arises from a complex array of factors that include air pollution (ozone, SO_2 , acid rain, etc.) along with climate stress (i.e., drought), forest management practices, the age of stands, etc. Acidified rain could change the nutrient balance of soils (magnesium, potassium, and calcium) and mobilize toxic metals (aluminum, cadmium, zinc, etc.).

Damage to buildings is frequently seen as an important impact of acid rain, perhaps because we confront our urban fabric almost every day. It is exposed to the ravages of high concentrations of air pollution, which means that buildings have long been disfigured by sooty crusts. Hidden underneath these crusts damage takes place through the oxidation of deposited SO_2 . Stones build up thick gypsum (calcium sulfate) layers and metals are also prone to attack. In general, the deterioration of metal work and, to a lesser extent, stone has declined as SO_2 concentrations have decreased in urban air.

There is now a decrease in the sulfur deposited in rain over Europe. This has led to complaints that some agricultural crops are now sulfur deficient. Although acid rain provided sulfur for crops, it is obviously important to remember its large-scale harmful effects before regretting its gradual elimination. Even though sulfur deposits have decreased in Europe, the acidity of rain has not always fallen to match this decline. Increases in nitric acid in air (from nitrogen oxides produced during combustion) and a decline in the alkaline content of the atmosphere may account for this. Today the acidification of rain has shifted geographically to tropical regions with fast-growing economies. Here there are new problems on ecosystems and land types quite different from those affected in Europe and North America.

Aerosol Sulfur and Climate

Sulfate in the atmosphere is present some of the time in acid aerosols, most commonly sulfuric acid or ammonium bisulfate. The sulfuric acid aerosol is typically present at diameters of 2–3 μm . This makes the particles excellent cloud condensation nuclei (CCN), but also a potential threat to human health when they are found concentrated in urban air. Sulfates, nitrates, and methanesulfonates are frequently found at enhanced concentrations on sea salt aerosols as these strong acids can displace as much as 90% of the chloride as hydrogen chloride, which degases to the atmosphere.

Sulfate aerosols appear to have an important role in controlling climate. The CO_2 -driven greenhouse effect provides a link between increases in global temperature and rising emissions of CO_2 from fossil fuels. SO_2 is also a product of much fossil fuel use and results in the presence

of sulfate particles in the atmosphere. These particles are likely to increase the number of CCN and hence the reflectivity of clouds. This would enhance the albedo of the Earth and lessen the temperature increase imposed by anthropogenic CO_2 emissions. The cooling effect, although difficult to estimate, is only a fraction of the increase from greenhouse gases.

Aerosols are incorporated into the well-known Gaia hypothesis, which sees the Earth as a self-regulator entity, particularly in terms of its temperature. One of the main ways in which atmospheric processes have been interpreted within the Gaia concept has been the potential for DMS emissions to stabilize temperature, against changes imposed by shifts in solar irradiance (Figure 3). This is known as the CLAW hypothesis, after Charlson, Lovelock, Andreae, and Warren, who first suggested it in 1987. It sees long-term climate as part of a feedback loop in which warmer temperatures would increase phytoplanktonic activity in the oceans. This in turn would increase emissions of DMS. Higher DMS concentrations in the atmosphere would increase sulfate containing CCN and thus cloudiness and albedo. This would lead to lower temperatures. It is an attractive and popular vision of the biological mediation in global climate, although proof from ice cores has yet to offer convincing proof for this concept of climate control.

Despite the size of the natural sulfur reservoirs, combustion of fossil fuels, mining, agriculture, and the drainage of large saline basins such as the Aral Sea have had a major impact on the sulfur cycle. Windblown sulfate dusts and acid rain have increased, and although emissions may have shifted away from the North Atlantic sector in recent decades, anthropogenic impacts on sulfur cycles will remain an important consideration in developing regions for some time to come.

Figure 3 Schematic representation of the CLAW hypothesis. Here phytoplanktonic activity in the oceans affects the emissions of DMS. Its oxidation can form sulfate-containing CCN and increasing cloudiness and albedo, which would lead to lower temperatures. If these lower temperatures cause the phytoplankton to produce less DMS, climate could effectively be controlled.

Synopsis

Bromine compounds cycle between the oceans, atmosphere, and land and in the atmosphere reactive bromine can lead to substantial destruction of ozone, both in the troposphere and in the stratosphere. Furthermore, bromine compounds play an important role for the oxidation of dimethylsulfide and mercury. The sources, sinks, and atmospheric chemistry of bromine are described in this article.

Overview and Significance of Bromine Cycle

Bromine is the second element of the halogen group and occurs naturally in the environment mainly as bromide salts in small amounts in crustal rock from where it has been leached and then accumulated in the oceans. It is commercially extracted mainly from seawater and Dead Sea waters. It further occurs naturally in soils and is taken up by vegetation and also from ocean water by marine algae, which synthesize a large range of organic bromine compounds which can be released to the ocean and atmosphere. Bromine cycles between the compartments of ocean, atmosphere, and land. In the atmosphere, inorganic bromine quickly cycles between the gas and particulate phase, however many details of this cycling are still ill-quantified. Organic bromine compounds are used commercially as flame retardants, pesticides (fumigants, mainly CH_3Br) and bromine was also used as an antiknocking agent in unleaded fuels. Many of these compounds (especially halons) play an important role in stratospheric ozone depletion (see **Stratospheric Chemistry Topics**: Halogens; Reactive Nitrogen (NO_x and NO_y); HO_x ; Hydrogen Budget; Halogen Sources, Anthropogenic; Halogen Sources, Natural (Methyl Bromide and Related Gases); Overview). In the troposphere bromine plays a role in ozone destruction, the oxidation of dimethylsulfide and elemental mercury. Global models suggest that bromine chemistry is responsible for 5–15% of the loss of tropospheric ozone. The chemistry of bromine is closely linked with that of the halogens chlorine and iodine. Chlorine and bromine, and to a lesser extent iodine, are often coemitted from the oceans and vegetation. Cross-reactions between chlorine, bromine, and iodine speed up their atmospheric cycling and amplify their relevance for atmospheric chemistry. See **Figure 1** for an overview of the most important atmospheric bromine processes.

Sources

The anthropogenic sources of bromine-containing compounds (halons, anthropogenic CH_3Br) are mainly of interest for the stratosphere, and are discussed in detail in the articles, **Stratospheric Chemistry Topics**: Halogens; Reactive Nitrogen (NO_x and NO_y); HO_x ; Hydrogen Budget; Halogen Sources, Anthropogenic; Halogen Sources, Natural (Methyl Bromide

and Related Gases); Overview; therefore, in this section we focus on natural sources. **Table 1** summarizes this information.

Sea Spray

Bromine is present as a trace compound in ocean water (about 0.85 mmol l^{-1}). It is supplied by riverine input and has a residence time of about 10^8 years. Sea spray aerosol is formed by wave action and bursting of gas bubbles that become entrained into the water at the sea surface. This results in the production of small particles that contain seawater. As bromide is present in seawater, production of sea spray aerosol is globally the main source of bromine to the atmosphere and accounts for $3.44\text{--}25.6 \text{ Tg year}^{-1}$ (range due to uncertainty in sea salt flux). The lifetime of particulate bromine in the atmosphere is determined by two factors: the lifetime against deposition of sea spray aerosol and the timescale of photochemical release of bromine to the gas phase. Bromide has been measured in marine aerosol since the 1960s and very often the ratio of $\text{Br}^-:\text{Na}^+$ is smaller in airborne particles than it is in the ocean. This indicates loss of bromine to the gas phase as the exchange of bromine between the gas and particulate phase is well documented from laboratory studies but no mechanism for the release of Na^+ from particles is known. Particulate bromine measurements show very large bromine depletions (10–100%) in aerosol particles with diameters greater than $1 \mu\text{m}$. Interestingly, smaller particles often show an enrichment of bromine compared to seawater which is not understood yet.

Polar Regions

In the early 1980s, sudden dramatic decreases in ozone concentrations were measured in the Canadian Arctic spring boundary layer. Soon they were linked to bromine chemistry but the exact bromine liberation mechanism is still somewhat unclear. These events have since been found to be very widespread both in the Arctic and Antarctic boundary layer in spring. What could be established is that a very efficient autocatalytic reaction cycle leads to the liberation of bromine from condensed phase bromide:

Figure 1 Overview of the most important atmospheric processes involving bromine. RGM stands for reactive gaseous mercury (Hg^{II}) and Br_x for photolyzable bromine compounds. Modified from Saiz-Lopez, A., von Glasow, R., 2012. Reactive halogen chemistry in the troposphere. Chemical Society Reviews 41, 6448–6472.

Table 1 Natural sources of bromine to the atmosphere

	Global source strength (Tg (Br) year^{-1})	Comment
Sea salt aerosol	3.44–25.6	Estimated from Br/Na ratio in seawater and sea salt fluxes from literature
Volcanoes	0.005–0.015	Pyle and Mather (2009)
Ocean exchange of CH_3Br	Source: 0.035 Sink: 0.041 Net: –0.006	WMO (2011)
Ocean exchange of CH_2Br_2	0.057–0.28	WMO (2011)
Ocean exchange of CHBr_3	0.12–1.4	WMO (2011)
Land-based vegetation, incl. salt marshes (CH_3Br)	0.014	WMO (2011)

Local lifetimes: $\text{CH}_3\text{Br} \sim 1$ year; $\text{CH}_2\text{Br}_2 \sim 120$ days; $\text{CHBr}_3 \sim 24$ days.

In this reaction cycle, ozone is destroyed very rapidly. Furthermore the uptake of one bromine atom (in the form of

HOBr) leads to the release of two bromine atoms (in the form of Br_2), hence this autocatalytic cycle has been named the ‘bromine explosion’ mechanism due to the ‘explosive’ growth of gas phase bromine concentrations. The source of the bromide that is involved in this reaction cycle is the ocean. Initially marine biogenic organic bromine gases were suspected to be the source of bromine, but this was soon refuted. Under some conditions however biogenic bromine gases can play a role as an additional source of bromine (see below). Upon freezing of seawater the salts contained in it are expelled from

the ice lattice and largely drain into the ocean, but are also present as deposits on top of first-year sea ice. It is possible that the bromine explosion happens on these deposits. Comparisons of satellite images of BrO and first-year sea ice have shown a strong spatial correlation. Furthermore, release from surface and blowing saline snow has been suggested as an important source of bromine in polar regions. Snow and ice as well as airborne particles can also act as substrates where the bromine explosion takes place. These condensed phases furthermore act to convert less reactive bromine compounds (e.g., HBr) to photolyzable bromine species (e.g., Br₂). Reactive bromine compounds have also been measured in the polar free troposphere pointing to vertical transport either upwards from the boundary layer into the free troposphere (e.g., through convection over regions of relatively warm open ocean, so-called open leads) or downwards from the stratosphere. The chemistry of bromine and chlorine is closely coupled and a role for chlorine in bromine release has been suggested to be of relevance at least under some conditions. Figure 2 summarizes the sources of bromine in the spring polar boundary layer.

Salt Lakes

In salt lakes large areas of salt are exposed to the atmosphere either as evaporites or highly saline surface waters. The bromide content and acidity of salt lakes varies considerably. Very strong bromine explosions have been found in the Dead Sea area with BrO mixing ratios of up to 200 ppt. Model calculations were able to reproduce the measured BrO values when they assumed the 'bromine explosion' mechanism to take place in large areas of exposed salt as well as the Dead Sea surface waters; bromine release from saline aerosol is not enough to reproduce the measured BrO values. Smog chamber experiments were able to reproduce the release of

photolyzable bromine from dry salt pans. BrO was also measured above other salt lakes such as the Salar de Uyuni in Bolivia. BrO was not detected above some salt lakes where measurements were made, possibly hinting at the bromine release being a function of the pH of the soil/salt lake (low pH leading to more release). Salt lakes might also play a role as source of natural halogenated organic gases, but this remains to be quantified.

Salt lakes provide unique 'natural laboratories' to study tropospheric halogen chemistry and bromine chemistry in particular but a more than regional impact on tropospheric chemistry is unlikely.

Volcanoes

The emission of HBr from volcanoes, especially arc volcanoes, has been known for a fairly long time, but the conditions in volcanic plumes were assumed to be rather unreactive except for an equilibration between the gas and particulate phase. In the early 2000s, however, BrO was detected in the plume of the passively degassing volcano Soufrière Hills on Montserrat in the Caribbean. Since then BrO was detected in the plumes of other volcanoes, both from passive degassing (e.g., Etna, Sicily; Masaya, Nicaragua; Villarica, Chile; Nyiragongo, Congo; Mt Erebus, Antarctica) but also from explosive eruptions (e.g., Kasatochi, Alaska; Eyjafjallajökull, Iceland). Satellite investigations were able to detect BrO in the plumes of many but not all probed volcanoes, which can likely only partly be explained by the coarse ground pixels and other instrumental limitations.

In order to account for the dilution of the plume with background air, often the ratio of a reactive compound, such as BrO, and a very unreactive compound such as SO₂ is used to investigate chemical processing in volcanic plumes as taking

Figure 2 Sources of halides in the polar boundary layer. A range of salinity values is indicated for the various reservoirs. PSU stands for practical salinity unit. From Abbatt, J.P.D., Thomas, J.L., Abrahamsson, K., Boxe, C., Granfors, A., Jones, A.E., King, M.D., Saiz-Lopez, A., Shepson, P.B., Sodeau, J., Toohey, D.W., Toubin, C., von Glasow, R., Wren, S.N., Yang, X., 2012. Halogen activation via interactions with environmental ice and snow. *Atmospheric Chemistry and Physics* 12, 6237–6271, reproduced with permission of the authors.

this ratio effectively cancels out dilution in the atmosphere. At several volcanoes the BrO/SO₂ ratio in the volcanic plume was very low near the crater rim but increased with distance (order of several 10 km). This shows that BrO is being produced in the early plume. Model calculations confirmed that the bromine explosion mechanism involving volcanic HBr and acidic aerosol particles can explain the observed BrO and the rise in BrO/SO₂ ratio. These studies also showed that bromine cannot be present only as HBr when emitted by the volcano but that some divergence from thermodynamic equilibrium producing e.g., Br₂ must occur, likely within the crater where oxygen-rich air is mixed with hot volcanic volatiles, in order to explain the very rapid rise in the BrO/SO₂ ratio.

The global source of bromine from volcanoes is rather small compared to other sources (see Table 1); however, the emissions from most volcanoes are directly into the free troposphere or stratosphere where the atmospheric lifetime of inorganic bromine is much longer than in the boundary layer.

Ocean: Organic Gases

It is well established that bromine-containing organic gases (e.g., CH₃Br, CHBr₃, CH₂Br₂, CH₂IBr) are produced in the marine environment. Once in the atmosphere these gases are broken down by photolysis or chemical reactions, which release reactive bromine. The organic bromine gases have a wide range of lifetimes in the atmosphere ranging from a year for CH₃Br to weeks for CHBr₃ and about 1 h for CH₂IBr. Information on CH₃Br, the longest lived of the organic bromine gases, can be found in Section Stratospheric Chemistry and Composition. The most abundant short-lived organic gases are CHBr₃ and CH₂Br₂ and the formation pathways for these compounds are believed to be principally biological. Marine seaweeds and diatoms are known sources of CHBr₃ and CH₂Br₂. The main production pathway is believed to involve vanadium- or heme-dependent haloperoxidases. These enzymes catalyze the breakdown of H₂O₂ through the two-electron oxidation of bromide yielding hypobromous acid (HOBr), which can then brominate electron-rich organic substrates. In marine environments the oxidation of bromide is primarily catalyzed by bromoperoxidases. The physiological role of haloperoxidase activity in marine organisms is yet to be established, but it has been proposed that they are involved in defense against oxidative stress and/or their inorganic or organic products act as grazing deterrents. A functional bromoperoxidase has recently been identified in strains of the marine cyanobacterium *Synechococcus* sp. so these organisms may also be involved in organic bromine gas formation.

The organic bromine gases are typically found at picomolar concentrations in seawater with CHBr₃ generally found at the highest concentrations (up to 10³ pM). CHBr₃ and CH₂Br₂ have been found to be supersaturated over large areas of the oceans with their concentrations and emission rates highly variable over spatial and temporal scales. Mean background tropospheric mixing ratios of CHBr₃ and CH₂Br₂ are in the range of 1–2 ppt. Emission source strengths for the organic bromine gases from the oceans currently have large uncertainty with estimates ranging from 120 to 1400 Gg Br year⁻¹ for CHBr₃ (note that the upper limit is likely too high) and 57–280 Gg Br year⁻¹ for CH₂Br₂. On a global scale this is

considerably lower than that from sea salt aerosol (Table 1), but the contribution from organic bromine gases to total inorganic bromine in the atmosphere is likely to be more important on a regional scale.

Anthropogenic Sources

The main anthropogenic uses of bromine are as flame retardant (mainly halons), pesticide (mainly CH₃Br), and additive to petrol as an antiknocking agent. Due to its role in stratospheric ozone depletion the use of halons and anthropogenic CH₃Br has been limited and declined substantially. This is described in detail in articles **Stratospheric Chemistry Topics: Halogens; Reactive Nitrogen (NO_x and NO_y); HO_x; Hydrogen Budget; Halogen Sources, Natural (Methyl Bromide and Related Gases); Overview**. Further anthropogenic sources of bromine include water purification. In some countries bromine is used as an agent for water purification, but even if drinking water is mainly chlorinated, bromine will be present as impurities. The same is true for emissions from cooling towers where cooling water is treated with halogens to limit algal growth.

Loss

As mentioned above, inorganic bromine compounds can cycle very quickly between the gas phase and particulate phase so that uptake of the fairly unreactive HBr on to particles is not necessarily the end of the atmospheric life cycle as it can be released again from particles in reaction cycles such as the bromine explosion mechanism. Eventually the loss of bromine compounds however is either through dry deposition of gases or bromine-containing particles to the surface or wet deposition (wash out) of particulate bromine or scavenging of soluble bromine gases by precipitation. Bromine can then be stored in soils or vegetation, from where it can again be released to the atmosphere, or is transported to the oceans through rivers.

The exchange of brominated compounds between the troposphere and stratosphere is often referred as sink for one and source for the other atmospheric compartment.

Tropospheric Chemistry

The tropospheric chemistry of bromine is closely linked to that of chlorine and iodine. Furthermore large similarities are present to stratospheric bromine chemistry. The cycling between the gas and condensed phase (such as aerosol particles, cloud droplets, saline solutions on the surface) is an important element of halogen cycling. The 'bromine explosion' mechanism was already explained; in the following further important reaction cycles are shown. X symbolizes a second halogen atom (Cl, Br, I). Bromine atoms react very quickly with O₃ producing BrO:

Even though this reaction destroys O₃, the most likely fate of BrO is photolysis:

From this reaction sequence it becomes obvious that it is more helpful to think in terms of the odd oxygen family ($O_x = O_3 + O + O(^1D) + NO_2 + 2NO_3 + 3N_2O_5 + HNO_4 + ClO + 2Cl_2O_2 + 2OCLO + BrO + IO + 2OIO$) when quantifying ozone loss. Odd oxygen is only lost if the product of a reaction involving odd oxygen, such as BrO , does not produce another member of the odd oxygen family. Hence the following reactions are 'real' ozone, or, more precisely, odd oxygen loss reactions:

or

Note that in the first reaction two members of O_x are being destroyed. This reaction also shows the link between various halogens; the reaction rates of the interhalogenoxide reactions are very fast, leading to very rapid ozone loss. Halogen-induced ozone loss has been suggested to be responsible for about 30% of photochemical ozone loss in the marine boundary layer and 5–20% in the global troposphere. Another cross-reaction sequence, similar to the bromine explosion, was shown to occur in the aqueous phase:

Instead of degassing, $BrCl_{aq}$ can also undergo the following sequence, depending on the relative concentrations of Cl^- and Br^- in the condensed phase, leading to the release of Br_2 :

In regions with high NO_x , $BrONO_2$ can constitute a significant fraction of gas phase bromine. It can be photolyzed, decompose or react on surfaces producing $HOBr$, $BrCl$, or Br_2 depending on the surface it reacts on. Under high NO_x conditions the reaction

can shift the NO to NO_2 ratio. Even though this reaction does not constitute a sink of O_x , it shortcuts the formation of O_3 as under most other circumstances the oxidation of NO to NO_2 is a gain of O_x . $HOBr$, which is produced in the reaction of BrO with HO_2 , can in addition to uptake on a surface also be photolyzed:

Figure 3 Global annual mean budget of tropospheric inorganic bromine (Br_y) in a state-of-the-art global atmospheric chemistry transport model (GEOS-Chem). The main reactions are indicated. Inventories are given as masses (Gg Br), with mixing ratios ($pmol\ mol^{-1}$) in square brackets. Rates are given in units of $Gg\ Br\ s^{-1}$. Read 6.3(-5) as 6.3×10^{-5} . HBr accounts for 55% of Br_y loss by deposition. Sea salt aerosol debromination is the dominant global source of Br_y , but is mainly confined to the marine boundary layer, where Br_y has a short lifetime against deposition. It accounts for 48% of the Br_y source in the global free troposphere. This sequence changes the OH to HO₂ ratio, which is also important for ozone formation.

Unlike chlorine atoms, bromine atoms cannot efficiently attack alkanes so only the reactions with aldehydes such as HCHO are important links between (oxygenated) volatile organic compounds and bromine:

BrO is an efficient oxidant of dimethylsulfide (CH₃SCH₃, DMS), a biogenic gas released from the oceans:

The breakdown products of DMS can lead to the growth of existing particles in the atmosphere and under certain conditions the nucleation of new particles. Further links between the bromine and sulfur cycles have been suggested involving the oxidation of S(VI) to S(VI) in the aqueous phase.

Strong links between the cycles of mercury and bromine have been found. Mercury is a toxic gas but in its main atmospheric reservoir, elemental Hg (Hg⁰), it is mostly harmless and has a lifetime of about a 1 year. However, if oxidized by OH or bromine:

mercury is rather soluble and the atmospheric lifetime is reduced to days. Once deposited it can be methylated and enter the food chain where it accumulates and causes most damage in species that are higher up in the food chain.

Summary

Bromine has very strong natural (e.g., sea spray aerosol, salty surfaces in polar spring, volcanoes, salt lakes, organic brominated gases) and anthropogenic (e.g., halons, CHBr₃) sources. Its chemistry is linked to that of chlorine and iodine. In the troposphere bromine plays a role for ozone destruction, DMS and mercury oxidation and in the stratosphere it plays a key role in ozone destruction.

Figure 3 shows the tropospheric budget of bromine according to a recent global modeling study. Table 2 provides an overview of tropospheric measurements of reactive bromine species.

For stratospheric chemistry, often use is made of the terms product gas (PG) and source gas (SG). SGs are those that have not undergone any chemical change since emission whereas

PGs are breakdown products. The inorganic gases mentioned here are all PGs but transport into the stratosphere is limited due to their usually rather large solubilities especially when compared to organic SGs and PGs. See the Stratospheric composition and chemistry section for more details.

Heavy Metals

TD Jickells and AR Baker, University of East Anglia, Norwich, UK

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Metals, other than mercury (0), travel in the atmosphere associated with aerosols. Emission sources include soil dust and sea spray, as well as anthropogenic emissions. Source strength estimates are presented and these show that the relative importance of anthropogenic and natural sources are very different for different metals. This difference, along with atmospheric cycling discussed, leads to differences in aerosol size distribution, atmospheric residence time, solubility in rainwater and environmental impacts. Hg(0) is gaseous, behaves very differently to other metals with a much longer atmospheric residence time.

Introduction

'Heavy metals' is a widely used but poorly defined term. This article will consider all metallic elements in the periodic table except those in groups 1 and 2. This definition will include metals, such as aluminum, which are not heavy in terms of their atomic weight but are emitted, transported, transformed, and deposited via the atmosphere in a similar way to other true heavy metals. Mercury is the only metal to behave very differently since it exists in the atmosphere in the gas phase rather than on aerosols. In the context of global biogeochemical cycling, atmospheric transport of heavy metals is a major transport route and one that has for some metals been significantly perturbed by human activity. The following sections will briefly describe the sources of some heavy metals to the atmosphere, their transport and cycling through the atmosphere, and their subsequent deposition, and will also consider the biogeochemical significance of the atmospheric transport rate. Because of its fundamentally different behavior, a separate section is devoted to mercury.

Sources

Metals are emitted to the atmosphere from a wide range of sources. Some of these emissions are entirely natural, such as from volcanoes or from biological emissions from land and the oceans. Others arise from natural processes that may have been

changed by human activities such as the formation of wind-blown dust or biomass burning. Similarly, sea salt formation is a natural process, but its significance as a source of metals to the atmosphere may have been modified by human perturbation of the concentrations of these metals in seawater, as will marine gaseous mercury emissions. Other sources of metals to the atmosphere are essentially entirely anthropogenic, arising from combustion processes and industrial activity.

Table 1 lists best estimates of fluxes to the atmosphere from the known sources for a group of metals whose fluxes are thought to have been significantly modified by human activity. In general fossil fuel combustion and metal production dominate the anthropogenic emission sources of these metals. The table is not intended to represent a comprehensive list of sources. Indeed, for many metals we do not know sources well. Furthermore, fluxes from human activity can change dramatically with time. This is particularly evident in the case of lead. Emissions of lead worldwide, for instance, have increased more than 25-fold. Even in remote areas of Europe, it is possible to show increasing lead concentrations in sediments dating back 2000 years, associated with its use by the Romans. Concentrations increased further as populations and industrialization developed over the last 1000 years. The biggest increase, from the 1950s, was predominantly due to the use of lead additives in automobile fuels. This source has declined very rapidly from the 1980s onward as a result of the removal of such additives. Measurements of the isotopic composition of lead have been a particularly powerful tool for tracing the changes in lead

Table 1 Worldwide emissions of trace metals (10^9 g per year)

Source	Arsenic	Cadmium	Copper	Lead	Selenium	Zinc
Wind-blown soil	2.6	0.2	8	3.9	0.2	19
Sea spray	1.7	0.1	3.6	1.4	0.5	0.4
Volcanoes	3.8	0.8	9.4	3.3	0.9	9.6
Forest fires	0.2	0.1	3.8	1.9	0.3	7.6
Continental biogenic emissions	1.6	0.2	2.9	1.5	3.7	5.1
Marine biogenic emissions	2.3	0.05	0.4	0.2	4.7	3.0
Total natural emissions	12	1.3	28	12	10.3	45
Total anthropogenic emissions in the mid-1990s	5	3	26	119	4.6	57

Natural emissions based on Nriagu, J.O., 1989. A global assessment of natural sources of atmospheric trace metals. *Nature* 338, 47–49 and anthropogenic emissions on Pacyna, J.M., Pacyna, E.G., 2001. An assessment of global and regional emissions of trace metals to the atmosphere from anthropogenic sources worldwide. *Environmental Reviews*. 9, 269–298.

sources. The use of isotopic measurements in other metals, to trace their sources, transport, and transformation processes, is beginning to be developed, with recent results published for Fe, Nd, and Hf.

Thus **Table 1** serves only to estimate the wide range of specific natural sources that are important for at least some elements, and the scale of perturbations of the total fluxes arising from human activity. The elements listed in **Table 1** have been selected to represent those for which we know that human perturbations are large. For many other metals such as iron, aluminum, and manganese, perturbations appear to be much smaller. This is illustrated in **Table 2**. Here the data are based on direct measurements of the metals in the atmosphere, which are expressed as enrichments of the observed concentrations over those predicted, if soil dust was the only source. As is evident from **Table 1**, this assumption of a soil source is simplistic, but large enrichments such as seen in **Table 2** for As, Cd, Cu, Pb, Se, and Zn do demand that there are large sources in addition to soil dust. In the case of a few metals such as selenium, it is likely that other natural sources, such as biological emissions of alkylated selenium compounds from seawater, are responsible for the enrichments. However, in most cases it is generally accepted that the large enrichments reflect the fact that anthropogenic emissions are now of comparable magnitude to natural sources for some metals as illustrated in **Table 1**.

Transport and Transformation

Metals emitted to the atmosphere with soil dust retain this association and hence, like soil dust itself, are associated with relatively large aerosols of an equivalent aerodynamic mass median radius of 0.5–2 μm during long-range atmospheric transport. Large-sized particles will be found close to sources or occasionally during highly energetic long-range transport. Metals derived from bursting of bubbles in seawater are associated with sea salt particles that typically are again associated with larger aerosol particles and have radii of 1–5 μm . By

contrast to these metals associated with aerosol particles formed directly by physical processes, metals released as gases (either of biogenic origin or arising from hot combustion processes) condense onto existing particles on the basis of surface area. Hence, such metals will be associated with finer modes of aerosol.

During aerosol transport, cloud cycling can induce changes in size distribution, as different aerosol particles are incorporated into cloud droplets that subsequently evaporate to produce a mixed aerosol particle. Despite this complication, it is remarkable that the aerosol size distribution appears to be very effectively retained over very long transport distances, as illustrated by data from Enewetak Atoll in the central Pacific Ocean shown in **Table 3**, where the size distributions of metals with predominantly crustal and anthropogenic origins are still clearly different from each other, but similar to those of these metals close to sources, even at this remote location, thousands of kilometers from their terrestrial sources.

During atmospheric transport, aerosols containing metals will become hydrated and the metals may become solubilized. This solubilization process is highly pH-dependent, with all metals being more soluble at low pH. Crustal aerosol itself is often alkaline and hence high dust loadings may suppress solubility. In contrast, anthropogenic emissions of gases such as SO_2 and NO/NO_2 can acidify atmospheric aqueous solutions and thus promote solubility. Indeed, some trace metals are known to be able to catalyze oxidation of SO_2 , and hence a positive feedback enhancing solubility is possible. During long-range transport, aerosols will be cycled through clouds a number of times, thereby encountering a range of pH values that may include highly acidic cloud waters. There is evidence to suggest that such pH cycling is not completely reversible and that repeated cycles enhance the solubility of metals at a particular final pH relative to the initial aerosol solubility at the same pH.

In the case of iron, photochemical reactions can lead to the formation of OH radicals (eqn [I]), which are powerful oxidizing agents that link these metals to the cycling of many other components in the atmosphere. These reactions can also modify iron solubility because of the much greater solubility of Fe(II) compared to Fe(III).

Table 2 Average enrichments of metals in aerosols over the value expected, if soil dust is the dominant source based on samples collected from many sites around the world

<i>Metal</i>	<i>Enrichment</i>
Aluminum	1
Arsenic	190
Cadmium	1100
Cobalt	1.9
Copper	25
Iron	1.3
Lead	320

A further process that may significantly modify the behavior of trace metals during atmospheric transport and transformation is organic complexation. This process has been known to be important for many years in soil, freshwaters, and marine waters. It is now becoming clear that organic material represents a substantial component of many aerosols. This organic material is poorly characterized, but it is clear that some of the organic compounds, including relatively simple organic molecules such as oxalic acid as well probably as some more complex organic material, can chemically bind metals and significantly modify the metals' solubility, bioavailability, and photochemistry.

Deposition

Trace metal removal processes from the atmosphere are similar to those of other aerosol species, and involve wet and dry deposition processes. These are discussed elsewhere in this Encyclopedia and will not be described in detail here. However, a few important points arise that are of specific relevance to metals. First, wet and dry deposition processes are dependent on aerosol particle size. Metals associated with coarser material will therefore be removed more rapidly from the atmosphere than metals associated with finer aerosol particles. The component of the metals in aerosol arising from gas-to-particle conversion, predominantly the anthropogenic component, is therefore less efficiently removed than those components associated with soil dust or sea spray. Thus anthropogenic emissions in general not only increase emissions of metals to the atmosphere but also promote their long-range transport. This is probably one reason why the enrichments seen in Table 2 are greater than predicted from the ratio between natural and anthropogenic emissions (Table 1).

The effect of pH on metal solubility was noted earlier. This results in marked changes in solubilities of metals over rather narrow pH ranges that vary for all metals (Figure 1). This is important because the impact of the metals on the environment varies markedly depending on whether the metal is soluble or insoluble. However, this solubility will also depend on the pH of the receiving media, which will generally be less acidic than rainwater.

Mercury

Mercury is unique among metals because it exists predominantly in the gas phase in the atmosphere as Hg^0 . In this form it has long residence time of about 1 year compared to only a few

Figure 1 Effect of pH on the solubility (mass/mass) of copper, lead, and zinc in rainwater. Based on Jickells, T.D., 1997. Atmospheric inputs of some chemical species to the North Sea. *Ger. J. Hydrogr.* 49, 111–118.

days for aerosol-bound metals (including oxidized forms of mercury). Mercury has substantial, natural, terrestrial, biological (2.5×10^9 g per year), and marine (2.7×10^9 g per year) sources, together with a large anthropogenic emission (2.3×10^9 g per year). Atmospheric oxidation reactions slowly convert Hg^0 to $\text{Hg}(\text{II})$, in which form it is essentially nonvolatile and is removed rapidly to aerosols and deposited.

Biogeochemical Significance of Atmospheric Transport of Trace Metals

As noted earlier, the emissions of many metals to the atmosphere have been estimated to be increased markedly by human activity and are now a major route for global transport (Table 4). Atmospheric emissions, particularly fine-mode aerosols, lead to very effective long-range transport, as is evident from the enrichment of several trace metals in even the remote atmosphere (Table 2). The complex record of increasing atmospheric concentrations arising from industrialization is preserved in the ice caps, particularly of the Northern Hemisphere, and in corals in central ocean regions remote from riverine sources (Figure 2). Thus it is clear that atmospheric transport has resulted in contamination of remote environments by trace metals, though the evidence for deleterious effects arising from their contamination, and hence for pollution, is equivocal. Recent studies have documented that measures to reduce emissions of lead via its elimination from vehicle fuels have been very successful with concentrations now

Table 4 A comparison of atmospheric and riverine fluxes (10^9 g per year) of some trace metals to the oceans

Metal	Fluvial dissolved flux	Fluvial particulate flux	Atmospheric dissolved flux	Atmospheric particulate flux
Iron	1100	110 000	3200	29 000
Copper	10	1500	14–45	2–7
Lead	2	1600	80	10
Zinc	6	3900	33–70	11–60

Note particulate material is deposited in estuaries and hence the best measure of comparison in terms of impacts on the open ocean is probably of the total atmospheric flux and the riverine dissolved flux.

Based on Duce, R.A., Liss, P.S., Merrill, J.T., et al., 1991. The atmospheric input of trace species to the world ocean. *Global Biogeochemical Cycles* 5, 193–259.

Figure 2 (a) Concentration of lead in Greenland snow. (Reproduced from Wolff, E., 1995. In: Wolff, E., Bales, R.C. (Eds.), *Chemical Exchange between the Atmosphere and Polar Snow*. Springer-Verlag, Berlin, pp. 1–18.) (b) Concentration of cadmium in coral from Bermuda in the Sargasso Sea, Central Atlantic. (Reproduced from Shen, G.T., Boyle, E.A., Lea, D.W., 1987. *Nature* 328, 794–796.) Note high concentrations during the early twentieth century associated with industrialization with limited emission abatement then reduced emissions following basic emission control with a subsequent rise with increasing industrialization before a fall post-1970 with improved emission control.

falling to levels, which are equivalent to those of the early 1900s. For other metals such as cadmium, which do not have a dominant single source, as was the case for lead, there is evidence of reducing concentrations as a result of improving emission control at source, although this is balanced against increasing societal use of resources.

While atmospheric transport of some trace metals has increased due to societal emissions, that of others such as iron has been little changed. Iron fluxes have changed on longer timescales, being higher during the last glaciation owing to increased aridity and stronger winds. Over the last few years the role of atmospheric iron transport has attracted increasing interest as it has become clear that iron is a key nutrient for phytoplankton in the oceans and that in some areas remote from desert regions (the dominant sources of dust), phytoplankton growth may be limited by iron availability. Higher dust loadings during the last glaciation may have promoted high marine productivity and contributed to the lower atmospheric CO₂ levels and hence to a cooler climate. Furthermore, higher productivity may increase emissions of dimethyl sulfide

from the oceans, which would increase the acidity of clouds and promote increasing bioavailability of iron as well as increase global albedo and hence influence climate. This emphasizes the interconnected nature of global cycles and it has become clear over recent years that atmospheric cycling of trace metals is a very important component of the global biogeochemical cycle.

Iodine

LJ Carpenter, University of York, York, UK

Synopsis

Iodine was discovered as a new element two centuries ago. It is essential to human health, yet a substantial proportion of the world's population are at risk from a lack of dietary iodine. Natural processes within the oceans are responsible for the majority of atmospheric iodine. In the lower atmosphere, iodine undergoes a complex array of photochemical reactions that lead to ozone destruction and, in some cases, new particle formation, before being scavenged by aerosol. The nature and mechanisms for oceanic iodine emissions are still uncertain.

Discovery

The discovery of iodine was by a French scientist, Bernard Courtois (1777–1838), in 1811 in the process of making saltpeter (potassium nitrate, a major component of gunpowder) for Napoleon's army. Potassium carbonate, required for saltpeter production, had been previously extracted from the ashes of willow wood. However, the Napoleonic Wars had gone on for so long that supplies were exhausted, and seaweed was suggested as an alternative feedstock to wood ashes. After adding concentrated sulfuric acid to burnt seaweed, Courtois noticed a violet vapor cloud, which he suspected to be a new element (Courtois, 1813). Soon after, several other scientists including Désormes (1777–1862), Clément (1779–1841), Gay-Lussac (1778–1850), Ampère (1775–1836), and the English chemist Sir Humphry Davy (1778–1829) performed scientific investigations into this substance. Davy came to the conclusion that it was an element in its own right, with properties similar to those of chlorine. This new element was named iodine after a Greek word for 'violet colored' (Figure 1).

Commercial and Medicinal Importance of Iodine

Later, iodine gathered commercial interest for its antiseptic qualities, its use in photography, and also in the treatment of thyroid enlargement (goiters). As a component of the thyroid hormones thyroxine and triiodotyronine, iodine is central to

thyroid function in vertebrates. Severe iodine deficiency also causes reproductive and neurological damage, the latter termed cretinism and associated with developmental delays. The introduction of iodized salt since the early 1900s has eliminated iodine deficiency disorders in many countries, however, even today it continues to be a serious threat to global human health and the greatest preventable cause of mental retardation (The Lancet, 2008). According to the World Health Organization, in 2007 nearly 2 billion individuals, a third being of school age, had insufficient iodine intake. Individuals living inland (with a lack of marine, iodine-rich foods in their diet) and in third world nations are especially at risk, however, a trend toward lower discretionary salt use and consumption of more processed foods (using noniodized salt) means that there is a widespread risk of obtaining insufficient iodine from food (Figure 2).

Besides its use in iodized salt, iodine is required in numerous products including in solar cells as a component of the conducting electrolyte, in X-ray contrast media (substances which enable visualization of soft tissues in X-ray examination), as an effective broad spectrum bactericide to disinfect wounds and to sanitize surface water for drinking (as tincture of iodine or more recently povidone iodine which is less irritating to the skin and other tissues), in the industrial production of acetic acid and nylon fiber, and as a component of the polarizing film of liquid crystal displays. Iodine is also frequently utilized as a reagent in organic synthesis, employed in iodinations, oxidations, and as Lewis acid.

Production of iodine from kelps (brown seaweeds), which contain very high concentrations, was a major economic activity in coastal regions of France, Scotland, and Ireland in the nineteenth century. Today, nearly 90% of global iodine production is based in either Chile, from the mining and leaching of nitrate ores (caliches), or in areas of Japan from iodine-rich brines found in some natural gas and oil fields.

Sources of Iodine to the Environment

Anthropogenic releases of atmospheric iodine (such as fossil fuel combustion) are believed to be negligible on a global scale compared to natural sources. The latter are mainly of marine origin, with a lesser contribution from land sources. Over 110 iodine-containing natural products have been identified, most of which originate from marine organisms (Dembitsky, 2006).

Iodine from Marine Algae and Microbes

Biological pathways for the production of iodine compounds by microalgae (phytoplankton) and macroalgae have been identified. Production of mono- and polyhalogenated compounds is believed to occur via the enzyme-catalyzed oxidation of halide ions within the algal tissue. Mono-halogenated organics are produced via the enzyme methyl transferase, present in both micro- and macroalgae (Wuosmaa and Hager, 1990; Itoh et al., 1997). Production of polyhalogenated organic species is enabled by haloperoxidase enzymes, present in both macroalgal (Theiler et al., 1978) and microalgal (Moore et al., 1996) cultures. Haloperoxidases catalyze the oxidation of halides by hydrogen peroxide (H_2O_2), released as part of normal cell metabolism and during oxidative stress, and the resulting products react with available organic material within the apoplast (cell wall space) to form volatile organohalogenes (Theiler et al., 1978). Under conditions of oxidative stress, e.g., at elevated temperatures/light or when exposed to grazing, H_2O_2 would otherwise build up to high levels. Thus, the mechanism is essential for the health of the organism. As a consequence of these reactions, a large variety of volatile organic iodine compounds (VOICs) are emitted from both microalgae (Moore et al., 1996) and macroalgae (Laternus et al., 2000; Carpenter et al., 2000). Enhanced emissions have been found in some studies when the algae are subject to high illumination (Moore et al., 1996; Carpenter et al., 2000; Laternus et al., 2004). In contrast, Hughes et al. (2006) found no effect of high light stress on iodocarbon release by three species of marine phytoplankton.

The kelp *Laminaria* and related brown macroalgae are the strongest iodine accumulators among all living systems (Küpper et al., 1998), and produce substantial volatile iodine

emissions in coastal regions (Carpenter et al., 1999; McFiggans et al., 2004; Küpper et al., 2008). X-ray absorption spectroscopy shows that the accumulated form of iodine in kelps is iodide, which serves as a simple inorganic antioxidant, protecting the apoplast from high levels of reactive oxygen species (ROS) such as H_2O_2 (Küpper et al., 2008). Upon oxidative stress, a strong efflux of accumulated iodide occurs, resulting not only in organic iodine compounds, but also in molecular iodine (I_2) when the seaweed is exposed to air (McFiggans et al., 2004; Saiz-Lopez and Plane, 2004; Palmer et al., 2005). This mechanism occurs via a rapid heterogeneous reaction of gas-phase atmospheric ozone with liquid iodide (millimolar concentrations) on the kelp surface, leading to the release of I_2 at rates up to about 5 orders of magnitude higher than the combined iodocarbon emissions (Küpper et al., 2008). This phenomenon could be widespread over seaweed beds, since release of iodide during oxidative stress is observed in both brown and red algae (Truesdale, 2008; Chance et al., 2009) (Figure 3).

In the open ocean, biological mechanisms for iodine production include methylation of iodine by marine microalgae (phytoplankton) (Itoh et al., 1997) and by a wide variety of aerobic marine bacteria (Amachi et al., 2001; Amachi, 2008), production of polyiodinated organic compounds from phytoplankton containing haloperoxidase enzymes (Moore et al., 1996), and production from natural marine aggregates comprising a host of material including phytoplankton and bacteria (Hughes et al., 2008). Iodide-oxidizing bacteria, which oxidize iodide to I_2 and organic iodine have also been found in iodide-rich environments (Fuse et al., 2003; Amachi et al., 2005), but appear to be absent or present in very low concentrations in natural seawaters and terrestrial soils (Amachi et al., 2005).

Figure 3 A simple model of iodine metabolism in *Laminaria*. (a) When submerged and unstressed, the alga accumulates iodide from seawater mediated by vanadium haloperoxidase (turquoise). When oxidative stress occurs (red), iodide is released to detoxify ROS (including both aqueous H_2O_2 and gaseous O_3) at the kelp surface. During oxidative stress at high tide, iodide is released into the surrounding seawater. (b) At low tide, the ozone-scavenging reactivity of iodide on kelp surface results in the release of molecular iodine, whose photolysis initiates a series of reactions producing bursts of aerosol particles. From Küpper, F.C., Carpenter, L.J., McFiggans, G.B., 2008. Iodide accumulation provides kelp with an inorganic antioxidant impacting atmospheric chemistry. *Proc. Natl. Acad. Sci. U.S.A.* 105 (19), 6954–6958.

The biological significance of iodine accumulation has been proposed to be linked to the antioxidant properties of I^- (Küpper et al., 2008), and it is well known that I_2 is a highly active oxidizing agent that has strong bactericidal, fungicidal, and sporicidal activities (McDonnell and Russell, 1999). Whether the evolved volatile iodine species produced by marine algae have a biological function is currently unknown. They may simply be a by-product of the intra- and intercellular removal of the H_2O_2 from algal tissue (Manley and Barbero, 2001), alternatively they may also act to deter the grazing of zooplankton. These biological phenomena have, however, significant impacts on atmospheric chemistry on scales from the local and global (see Section *Reactive Iodine Species in the Atmosphere*).

Current 'bottom-up' global estimates of biogenic organoiodine fluxes to the atmosphere from macroalgae, extrapolated from incubation studies, are of the order of 10^8 – 10^{10} g of iodine per year (Manley et al., 1992; Laturnus et al., 2000; Carpenter, 2003). Similar extrapolation of microalgal production deduced from laboratory culture studies results in a contribution of 10^6 – 10^9 g of iodine per year in the form of methyl iodide (CH_3I) (Manley and de la Cuesta, 1997). Smythe-Wright et al. (2006) attributed extremely high CH_3I levels in seawater to biological production by the picoplankton *Prochlorococcus marinus*, suggesting this source alone could contribute 5.3×10^{11} g of iodine per year. In contrast, Brownell et al. (2010) found that the production of CH_3I by *P. marinus* can account for only a small fraction of the estimated global oceanic production. Bacterial production of CH_3I is estimated as 1.6×10^9 g of iodine per year (Amachi, 2008).

Estimates of the global organoiodine burden from sea–air flux measurements are much higher than typical bottom-up estimates. Extrapolating from coastal, shelf, and open ocean summer data, Jones et al. (2010) estimated a total global iodine flux of 1.1×10^{12} g of iodine per year, of which about half is from CH_3I (Butler et al., 2007; Jones et al., 2010), with the remainder dominated by chloroiodomethane (CH_2ICl) and diiodomethane (CH_2I_2) (both $\sim 20\%$). In the Atlantic shelf regions, the major single contributor to the flux appears to be CH_2ICl (~ 40 – 50% of the total organoiodine flux of ~ 30 – $40 \mu\text{mol (I)}$ per square meter per year in summer) (Jones et al., 2010; Archer et al., 2007), whereas CH_3I appears as the most important contributor in open ocean waters of the Atlantic (45 – 65% of the total flux; Jones et al., 2010). For both gases, fluxes tend to be higher over biologically active regions, as demonstrated by the English Channel shelf measurements of Archer (Archer et al., 2007) and the Irish continental shelf and Mauritanian upwelling measurements of Jones et al. (2010). Figure 4 shows measurements of CH_3I and CH_2ICl emissions from several studies in the open Atlantic Ocean, calculated from the measured partial pressure difference of the gas across the sea surface flux = $K_T (C_{\text{water}} - C_{\text{air}}/H)$, where H is the Henry's law coefficient and K_T is the wind-dependent gas transfer velocity (Nightingale et al., 2000).

Thus, it appears that either incubation studies fundamentally underestimate marine emissions, and/or that other oceanic sources are at play. Some evidence for the former comes from Hughes et al. (2008) who observed high monoiodinated organic production rates, approximately an order of magnitude greater than that reported for bulk natural water sample in natural marine aggregates (comprising a host of materials

Figure 4 Emissions of CH₃I and CH₂ClI from the open Atlantic Ocean. including diatoms, bacteria, and phytodetritus), possibly because of the copresence of high bacterial activity and organic material. These authors suggest that such detrital particles could be hotspots of production in the marine environment.

In coastal regions, atmospheric concentrations of both organoiodine compounds (Carpenter et al., 1999) and I₂ (Saiz-Lopez and Plane, 2004; Saiz-Lopez et al., 2006) are highest at low tide, consistent with emissions occurring from seaweed. A footprint model of I₂ emissions from seaweeds estimated the release of up to 510 μmol (I) per square meter per year of I₂ at low tide at Roscoff, France (Leigh et al., 2010; R. Leigh, personal communication), based upon species-specific I₂ emission rates parameterized from the laboratory study of Ball et al. (2010). Agreement between modeled and observed I₂ concentrations could only be obtained during the day if the model included an efficient recycling mechanism for I₂ in the atmosphere, equivalent to approximately 95% slower photolysis of I₂. This is contrary to current understanding and suggests either a substantial missing recycling or source component for I₂, or that unmodeled local emissions were present during this field study.

Abiotic Mechanisms in the Marine Environment

There is also evidence that nonbiological iodine sources are significant in the global inventory of iodine. The major source of CH₃I appears to be from sunlit irradiation of seawater (Moore and Zafriou, 1994; Bell et al., 2002). The suggested

mechanism is photochemical generation of methyl and iodine radicals from, respectively, dissolved organic matter and iodide present in the surface waters. Measurements in the North and tropical Atlantic have confirmed that surface saturation anomalies of CH₃I are correlated with light intensity and that the photochemical source of CH₃I is abiotic, and suggest that this route can support at least half of the average sea-to-air flux of 23 nmol m⁻² day⁻¹ (Happell and Wallace, 1996; Richter and Wallace, 2004). An additional dust-stimulated abiotic emission of CH₃I from the ocean or marine aerosol was suggested by Williams et al. (2007).

An additional abiotic contribution to the atmospheric iodine budget may arise from the reaction of atmospheric O₃ deposited at the sea surface with iodide to evolve I₂ (reactions [1] and [2]), as first proposed by Garland et al. (1980) and Garland and Curtis (1981). Recent work suggests that this could be an efficient mechanism for iodine emission from the open ocean (Carpenter et al., 2013). This is also the mechanism proposed to occur on kelp surfaces (Palmer et al., 2005), as discussed earlier.

Martino et al. (2009) proposed that reactions [1] and [2], followed by the reaction of HOI or I₂ with dissolved organic carbon (DOC) in the sea surface, also results in the production

of reactive organoiodine compounds including CH_2I_2 , CHClI_2 , and CH_3I . Production of polyhalomethanes from such reactions is known to occur during the disinfection of natural waters.

Another potential route to direct ocean surface production of small halogen molecules is via oxidation of halogen anions to their radical forms by photosensitizers such as chlorophyll or aromatic ketones, a known component of marine DOC, which in turn will lead to the formation of organic halogens in the presence of organic compounds in the sea surface microlayer (Jammoul et al., 2009). The oxidation is enhanced in the presence of atmospheric O_3 , which acts as an electron acceptor, thus promoting the cationic form of the photosensitizer.

Although suggestive of additional iodine sources, extrapolating these laboratory studies to the environment is not straightforward. However, some evidence for production of I_2 in surface seawater is provided from voltammetry measurements of $\sim 10^{-9} \text{ mol dm}^{-3} \text{ I}_2$ in some samples of surface coastal seawater (Möller et al., 1996).

Marine Destruction

Chemical depletion of volatile iodine compounds in the oceans can potentially play an important role in the extent to which they contribute to tropospheric photochemistry. Nucleophilic substitution by chloride ions (Cl^-) via an $\text{S}_{\text{N}}2$ mechanism is the major chemical sink of CH_3I , $\text{C}_2\text{H}_5\text{I}$, and $1\text{-C}_3\text{H}_7\text{I}$ in seawater (Zafriou, 1975; Zika et al., 1984; Elliott and Rowland, 1993; Jones and Carpenter, 2005), and is competitive with sea-air transfer for CH_3I . Chlorination reactions are however strongly temperature-dependent and at low temperatures hydrolysis (Elliott and Rowland, 1993; Jones and Carpenter, 2007) of CH_3I becomes competitive. In the case of $\text{C}_2\text{H}_5\text{I}$ and $1\text{-C}_3\text{H}_7\text{I}$, the Cl^- ion reaction occurs at a rate substantially slower than volatilization, except in waters of very high temperature ($\sim 25^\circ\text{C}$) (Jones and Carpenter, 2007). At equivalent rates, $2\text{-C}_3\text{H}_7\text{I}$ is depleted with respect to its reaction with Cl^- ions and hydrolysis, implying an $\text{S}_{\text{N}}1$ mechanism (Jones and Carpenter, 2007). In most oceanic conditions, abiotic chemical destruction of $2\text{-C}_3\text{H}_7\text{I}$ is competitive with loss from the ocean due to volatilization, i.e., chemical

breakdown in the oceans significantly limits the efficiency of $2\text{-C}_3\text{H}_7\text{I}$ transfer to the marine boundary layer (MBL). In regions where the seawater temperature is below $\sim 10^\circ\text{C}$ such as in polar waters, the majority of monoiodinated alkanes produced in the ocean will ultimately end up being emitted to the MBL to participate in tropospheric photochemistry. However, abiotic chemical destruction has the potential to significantly limit the oceanic emission of CH_3I and $2\text{-C}_3\text{H}_7\text{I}$ to the MBL in warm waters.

In contrast to the monoiodinated alkanes, polyhalogenated organoiodides undergo significant photolysis in surface marine waters (Martino et al., 2005; Jones and Carpenter, 2005; Jones et al., 2010). Surface photolysis results in a reduction of average daily sea-air fluxes by up to about 25% (although 20–80% at midday) for CH_2I_2 in tropical Atlantic waters, but has very little effect on the loss of CH_2ICl and CH_2IBr (Jones et al., 2010). About 30% of photolyzed CH_2I_2 produces CH_2ICl in seawater (Martino et al., 2005; Jones and Carpenter, 2005), representing a potentially significant route to this compound (Carpenter et al., 2007).

Lifetimes in seawater against chlorination, hydrolysis, and photolysis for temperatures of 0, 15, and 30°C , respectively, are shown in Table 1.

Terrestrial Halogenated Source Gas Emissions

Methyl halides are produced by a large number of terrestrial ecosystems, crops, and biota, including coastal salt marshes, freshwater wetlands, peatlands, forest soils, tropical forests, rice paddies, and wood-rotting fungi (Dimmer et al., 2001; Harper, 1985; Redeker et al., 2000; Rhew et al., 2001, 2000; Varner et al., 1999; Yokouchi et al., 2002). Terrestrial sources of CH_3I are together believed to comprise up to 80–110 Gg of iodine per year (Bell et al., 2002; Sive et al., 2007), comprising 18–50 Gg of iodine per year from rice paddies (Muramatsu and Yoshida, 1995; Redeker et al., 2000), ~ 6 Gg of iodine per year from natural wetlands (Dimmer et al., 2001), ~ 8 Gg of iodine per year from biomass burning (Bell et al., 2002), and 30 Gg of iodine per year from midlatitude terrestrial biomes (Sive et al., 2007). Keppler et al. (2000) proposed an abiotic route for alkyl halide production in soils and sediments from halide ion alkylation during the oxidation of organic matter

Table 1 Lifetimes (to the nearest year, month, week, or day) with respect to total chemical destruction of CH_3I , $\text{C}_2\text{H}_5\text{I}$, $1\text{-C}_3\text{H}_7\text{I}$, and $2\text{-C}_3\text{H}_7\text{I}$ at a range of seawater temperatures. Lifetimes with respect to simultaneous chlorination and hydrolysis are in bold, chlorination only in brackets, and photolysis only in italics. Photolysis lifetimes are calculated at 1 July, 12 p.m. in 54°N

Iodoalkane	Lifetime (0°C)	Lifetime (15°C)	Lifetime (30°C)
CH_3I	11 months (3 years)	7 weeks (11 weeks)	7 days (8 days)
$\text{C}_2\text{H}_5\text{I}$	11 months (11 years)	9 weeks (7 months)	10 days (2 weeks)
$1\text{-C}_3\text{H}_7\text{I}$	7 months (24 years)	8 weeks (1 year)	2 weeks (4 weeks)
$2\text{-C}_3\text{H}_7\text{I}$	4 months	12 days	1 day
CH_2ICl	<i>9 h $\pm$ 2 h</i>	<i>9 h $\pm$ 2 h</i>	<i>9 h $\pm$ 2 h</i>
CH_2IBr	<i>4.5 h $\pm$ 40 min</i>	<i>4.5 h $\pm$ 40 min</i>	<i>4.5 h $\pm$ 40 min</i>
CH_2I_2	<i>9 min $\pm$ 1 min</i>	<i>9 min $\pm$ 1 min</i>	<i>9 min $\pm$ 1 min</i>

From Jones, C.E., Carpenter, L.J., 2005. Photolysis of CH_2I_2 , CH_2ICl and CH_2IBr in water and seawater by solar radiation. Environ. Sci. Technol. 39, 6130–6137; Jones, C.E., Carpenter, L.J., 2007. Chemical destruction of CH_3I , $\text{C}_2\text{H}_5\text{I}$, $1\text{-C}_3\text{H}_7\text{I}$, and $2\text{-C}_3\text{H}_7\text{I}$ in saltwater. Geophys. Res. Lett. 34 (13).

by an electron acceptor such as Fe(III). The authors proposed that production of C1–C4 alkyl iodides from soils containing Fe(III) and iodide could be significant globally, although their data did not allow for an estimate of emission. Terrestrial sources for the di- and triiodated compounds have not been identified.

Summary of Iodine Sources

It is clear that of the few teragrams of iodine believed to be emitted per year to the atmosphere, the majority comes from the ocean. The volatile fraction of iodine in seawater is low: it exists predominantly as iodate, iodide, and nonvolatile dissolved organic iodine, with a total concentration of around 0.45 mM (Wong, 1991). Sea-salt aerosol particles, arising from evaporation of sea spray, are generally enriched in iodine by 2–3 orders of magnitude compared to concentrations in seawater (Sturges and Barrie, 1988; Baker, 2004). Thus sea-salt aerosol is a net sink of gaseous iodine (in contrast, it represents the main source of chlorine and bromine in the MBL), though it plays an important role in recycling gas-phase iodine. Photooxidation of emitted volatile organic and inorganic iodine species in air to soluble inorganic products allows a significant fraction of the iodine to partition to the aerosol phase, which is eventually removed by wet or dry deposition to the land or ocean. Thus the cycle provides a vital route for terrestrial uptake of iodine, an essential component of mammalian health as discussed in Section [Discovery](#).

The current estimate of global organoiodine emissions of ~1 Tg of iodine per year (Jones et al., 2010) (which equates to an average sea–air flux of ~20 μM of iodine per square meter per year) is rather higher than the depositional flux of I^- and IO_3^- in rainwater and marine aerosol into the southern North Sea of 6.3–9.2 μM of iodine per square meter per year (Baker et al., 2001). The total sea-to-air flux of iodine is likely to be higher due to chemical (Carpenter et al., 2013) and photochemical (Jammoul et al., 2009) mechanisms for production

of inorganic iodine from the ocean surface. The depositional flux does not include soluble organically bound iodine, which can make a significant or even major contribution to precipitation and marine aerosol iodine (Baker, 2005; Gilfedder et al., 2008). The contribution of different chemical and biological sources to gaseous iodine in the marine atmosphere is currently highly uncertain and requires further attention.

Reactive Iodine Species in the Atmosphere

Photoproduction of Iodine Atoms

Current understanding of the main features of iodine photochemistry in the MBL is shown in [Figure 5](#).

The cycle is initiated by photolysis of iodine compounds with lifetimes ranging from several days (CH_3I , $\text{C}_2\text{H}_5\text{I}$, $\text{C}_3\text{H}_7\text{I}$: Rattigan et al., 1997; Roehl et al., 1997), several hours (CH_2ICl : Rattigan et al., 1997; Roehl et al., 1997), an hour or less (CH_2IBr , Mössinger et al., 1998), about 5 min (CH_2I_2 : Roehl et al., 1997; Mössinger et al., 1998) to less than 10 s (I_2 – Saiz-Lopez et al., 2004) at midday in the lower troposphere. The more photoreactive iodo-carbons with two chromophores, e.g., CH_2I_2 and CH_2ICl , have been shown to be the most important organic iodine sources in the MBL (Jones et al., 2010). Although the lifetimes of the polyhalomethanes are controlled almost entirely by photodissociation, OH- and Cl-radical-initiated attack could account for 10–20% of the removal of CH_3I and compete with photolysis for removal of the propyl iodides (Cotter et al., 2001).

The iodine atoms arising from molecular or organoiodine breakdown almost exclusively react with O_3 forming the iodine monoxide (IO) radical and undergoing subsequent reactions, which alter atmospheric chemistry and physics, as described below. The ultimate fate of iodine is accumulation in particles in the form of iodide and iodate (Pechtl et al., 2006), typically occurring by the uptake of inorganic iodine (mostly INO_x , HIO_3 , and I_xO_y).

Figure 5 Atmospheric chemistry of iodine. Dashed lines represent photolysis reactions. Dotted lines represent volatilization from aerosol. IOPs, iodine oxide particles; X, Cl, Br, or I.

Atmospheric Observations of Gas-Phase Reactive Iodine Species

Coastlines

It has become clear that coastal regions offer a unique iodine-rich environment through direct emissions of very reactive molecular iodine (I_2) from seaweed (Dixneuf et al., 2009; Palmer et al., 2005; Saiz-Lopez and Plane, 2004; Huang et al., 2010). It was long established that seaweeds, particularly kelps, emit VOIC (Gschwend et al., 1985; Manley and Dastoor, 1987; Nightingale et al., 1995; Carpenter et al., 2000); however, it now appears that the inorganic iodide efflux leading to I_2 formation after an oxidative burst is some 3–5 orders of magnitude higher than organic iodine emissions (Küpper et al., 2008). Mixing ratios of I_2 of up to 93 pptv (peaking at night due to the fast photolysis of I_2) have been made at Mace Head and other coastal locations (Saiz-Lopez and Plane, 2004; Peters et al., 2005; Bitter et al., 2005; Saiz-Lopez et al., 2006; Huang et al., 2010). Such volatilization of I_2 from kelps exposed to air appears to explain the observations of coastal ‘bursts’ of iodine-containing ultrafine aerosol particles at low tide during the day (see Section *Aerosol Formation and Iodine Oxide Particles*) (O’Dowd et al., 1999, 2002b).

Differential Optical Absorption Spectroscopy (DOAS) measurements of IO were first reported at the coastal site of Mace Head, Ireland by Alicke et al. (1999), and since then numerous studies have indicated that IO is ubiquitous in the air above kelp-rich coastlines (Wada et al., 2007; Whalley et al., 2007; Mahajan et al., 2009; Commene et al., 2011). IO levels tend to peak during the day at low tide, consistent with production via the photolysis of seaweed iodine emissions. Nighttime IO mixing ratios of up to 3 pptv have also been observed (Saiz-Lopez and Plane, 2004) and attributed to the reaction of I_2 with the nitrate radical (NO_3) to give I atoms (Chambers et al., 1992), which are subsequently oxidized to IO by O_3 .

Point measurements of IO by laser-induced fluorescence (Whalley et al., 2007; Commene et al., 2011) and by cavity ring-down spectroscopy (CRDS) (Wada et al., 2007), of I_2 by broadband CRDS (Bitter et al., 2005; Leigh et al., 2009), and using diffusion denuders (Huang et al., 2010) reveal considerable spatial heterogeneity in coastal mixing ratios of reactive iodine species. IO mixing ratios measured by point techniques are typically an order of magnitude larger than those reported by long-path DOAS (LP-DOAS). Model simulations of such observations are consistent with I_2 emissions concentrated over the intertidal region of a few hundred meters (Leigh et al., 2009).

In addition to IO and I_2 , there have been several observations of OIO, and more recently I atoms at coastal sites. Using a resonance fluorescence technique, Bale et al. (2008) measured ambient I atom levels of up to 22 pptv during the day at Mace Head. At both Mace Head and a similar site with abundant seaweed at Roscoff, France, mixing ratios of OIO detected by LP-DOAS peaked at nighttime at 9–10 pptv and were below the instrument detection limit of ~ 2 pptv during the day, consistent with rapid photolysis (Gómez Martín et al., 2009; Mahajan et al., 2009). In contrast, high daytime OIO levels (>20 pptv) at the Gulf of Maine have been reported (Stutz et al., 2007).

Open Ocean

Evidence for the widespread occurrence of iodine chemistry, away from the influence of seaweed, comes from observations of IO off the north coast of Tenerife, Canary Islands (LP-DOAS; up to 3 pptv IO) (Allan et al., 2000), the northeast coast of Sao Vicente in the Cape Verde archipelago (LP-DOAS; 1–3 pptv IO) (Read et al., 2008; Mahajan et al., 2010a), and the Eastern Pacific upwelling region (multiaxis DOAS slant columns of IO) (Volkamer et al., 2010). In addition to these ground-based measurements, satellite slant columns indicate widespread levels of IO over tropical upwelling regions of the Pacific (Schönhardt, 2009; Schönhardt et al., 2008).

The presence of reactive iodine species can activate the release of bromine and chlorine via heterogeneous reactions on sea-salt aerosol (Vogt et al., 1999) and the combined presence of halogens in the marine environment acts synergistically to catalyze O_3 destruction (see Section *Ozone Destruction*). At Cape Verde, the result is a $\sim 50\%$ increase in photochemical O_3 destruction rates (compared to a hypothetical situation without halogens), with iodine responsible for about 2/3 of the halogen-related loss (Read et al., 2008; Mahajan et al., 2010a; Jones et al., 2010). Observed ozone depletion in this region cannot be explained in the absence of halogen compounds (Figure 6). Earlier measurements of O_3 in the remote MBL have also invoked halogen chemistry to explain measured diurnal variations (Dickerson et al., 1999; Galbally et al., 2000), albeit without direct evidence of the presence of halogen oxides.

Despite evidence of its effect on atmospheric chemistry, the sources of IO in the open ocean marine environment are unclear. Measurements of sea-air fluxes of organic iodine compounds in the region of Cape Verde (Jones et al., 2010) cannot be reconciled with the observations of IO, even given uncertainties in kinetic parameters, and suggest a significant additional source of iodine. Molecular iodine released via the heterogeneous reaction of O_3 on the sea surface has been invoked (Mahajan et al., 2010a; Jones et al., 2010). If indeed present as I_2 , the resulting atmospheric levels (up to 7 pptv at night) are close to current instrument detection limits (Mahajan et al., 2010a), thus it is not yet possible to verify whether an I_2 production mechanism operates efficiently over the open ocean.

Polar Boundary Layer

High levels of IO in the coastal Antarctic boundary layer have been inferred from differential slant columns (Frieß et al., 2001; mixing ratios up to 10 pptv) and directly from DOAS measurements (Saiz-Lopez et al., 2007; mixing ratios over 20 pptv). Satellite measurements show that IO is abundant over widespread areas of the Antarctic coast and continent (Saiz-Lopez et al., 2007; Schönhardt et al., 2008). These studies reveal a seasonal cycle in IO with a spring maximum followed by a decrease during summer and then a secondary maximum during autumn (Saiz-Lopez et al., 2007; Schönhardt et al., 2008). Though very similar in atmospheric behavior and mixing ratio to bromine oxide (BrO), the presence of IO was predicted to increase the rate of O_3 loss by a factor of 4 compared to the presence of BrO alone (Saiz-Lopez et al., 2007).

Gas-phase iodine chemistry in the Arctic appears to be less active and on a more localized scale than in the

Figure 6 Average hourly (a) BrO, (b) IO mixing ratios measured by LP-DOAS at the Cape Verde Atmospheric Observatory during November 2006–June 2007. Errors (1σ) are indicated as gray lines, and (c) measured and modeled average monthly values of ΔO_3 , defined as the observed daily O_3 destruction at Cape Verde in ppbv (parts per 10^9 by volume). The average loss over the period shown was 3.3 ± 2.6 ppbv per day between 09:00 and 17:00 h UT. The light blue line and symbols represent simulations using the global tropospheric chemistry transport model GEOSChem (with no halogen chemistry). Box model simulations with halogens (constrained using the IO and BrO measurements shown) and without halogens show that IO and BrO chemistry can account for the additional O_3 loss required within GEOSChem. Adapted from Figures 2 and 3 of Read, K.A., Mahajan, A.S., Carpenter, L.J., Evans, M.J., Faria, B.V.E., Heard, D.E., Hopkins, J.R., Lee, J.D., Moller, S., Lewis, A.C., Mendes, L., McQuaidm, J.B., Oetjen, H., Saiz-Lopez, A., Pilling, M.J., Plane, J.M.C., 2008. Extensive halogen-mediated ozone destruction over the tropical Atlantic Ocean. *Nature* 453 (7199), 1232–1235.

Antarctic. At Ny-Ålesund, Spitzbergen, IO was never measured above the detection limit, though total gaseous iodine (measured by neutron activation) reached 8 pptv (Martinez et al., 1999). At Alert, Canada, in springtime, measurements of IO were above the detection limit only on one occasion (Hönninger, 2002). However, IO was recently detected at Hudson Bay in the Canadian Arctic, with levels of up to 3.4 pptv of IO in air that had recently passed over open leads in the sea ice (Mahajan et al., 2010b). Calculations suggested that at the levels observed, IO could enhance the O_3 depletion potential of bromine by a factor of 3. Theoretical studies of the effect of iodine on mercury also suggest that atmospheric mercury depletion events in typical mixtures of bromine can be enhanced significantly by the presence of small amounts of iodine-containing compounds (Calvert and Lindberg, 2004).

The source(s) of reactive iodine to the polar atmosphere and the reason for apparently much more active iodine chemistry in Antarctica remain unknown, but a variety of mechanisms have been proposed. Recent Antarctic measurements suggest very high IO concentrations present in snow interstitial air (Frieß et al.,

2010), with an initial source of iodine postulated to be CH_3I produced in the marginal ice zone (MIZ) and deposited to the snow pack during transport inland. Mahajan et al. (2010b) use modeling studies to suggest that the emission of biogenic VOIC from coastal leads in the sea ice (polynyas) can account for the observed atmospheric concentrations of IO. Polynyas are known to be associated with high rates of biological activity and the dominant phytoplankton group is typically large diatoms, which are known to be an iodocarbon source. Inorganic sources of iodine (I_2 or HOI) to the polar atmosphere have also been suggested. Hill and Manley (2009) recently determined very high production rates of HOI and HOBr from polar marine diatoms (abundant under sea ice), much greater than the previously measured organic halogen rates of release. It is not yet clear how much, if any, of the reactive halogens (HOX and X_2) escape to the atmosphere, but Shaw et al. (2011) show that brine channels in consolidated (even fresh) sea ice offer a negligible trace gas diffusion pathway, though emission from open leads could be important.

Antarctica offers a more biologically active environment than the Arctic with thinner and more porous sea ice (e.g.,

Thomas and Dieckmann, 2003), which may explain the more active iodine chemistry there. At both poles, the occurrence of polynyas, open leads and the MIZ is likely to increase as sea ice continues to thin and retreat, which could enhance the rate of iodine flux to the atmosphere.

Terrestrial Environments: Salt Lakes and Volcanoes

Salt lakes and volcanoes represent environments containing very high halide levels, and both appear to be sources of gas-phase iodine (as well as bromine). Up to 10 pptv of IO have been observed over the surface of the Dead Sea (Zingler and Platt, 2005). The authors proposed the release of iodine from salt deposits via heterogeneous inorganic (IX where X = I, Br, Cl) iodine release induced by liquid phase ozone reactions or catalytic HOX interactions. From volcanoes, a global source strength of 0.11 Gg (range: 0.04–6.6) of iodine per year has been calculated from extrapolation of emissions of acidic iodine species from Mount Etna (Aiuppa et al., 2005).

Stratospheric Iodine

Calculations suggest that only relatively small amounts of iodine (compared with bromine and chlorine) transported to the tropical lower stratosphere, e.g., by tropical deep convection of organic iodine compounds, could make an important contribution to O₃ depletion there (Solomon et al., 1994). However, a number of measurements, made using both ground-based and balloon-borne instruments, have indicated that iodine plays only a minor stratospheric role with reported upper limit mixing ratios in the upper troposphere and lower stratosphere of below 0.2 pptv total inorganic iodine (I_T) (Wennberg et al., 1997; Berthet et al., 2003; Bösch et al., 2003; Pundt et al., 1998; Butz et al., 2009). In contrast, retrievals of differential slant column densities of IO measured using ground-based zenith-sky spectroscopy (Wittrock et al., 2000) suggest mixing ratios up to 0.8 pptv of IO in the high-latitude winter stratosphere technique. This has yet to be confirmed by *in situ* measurements of active iodine.

Atmospheric Chemistry of Iodine

The following sections summarize the current literature on atmospherically relevant reactions of iodine. For comprehensive details, the reader is referred to the 2003 and 2012 reviews in *Chemical Reviews* (Carpenter, 2003; Saiz-Lopez et al., 2012).

Ozone Destruction

Unlike chlorine and bromine atoms, which are reactive to a range of organic molecules, iodine atoms do not react with either saturated or unsaturated organic compounds. Reaction with O₃ forming the IO radical is their major fate. As noted in Sections [Open Ocean](#) and [Polar Boundary Layer](#), iodine is believed to be responsible for significant photochemical O₃ destruction in the marine and polar lower troposphere. This impact occurs mainly through three catalytic cycles, all of which regenerate I atoms from IO without concomitant O atom formation (which would lead to a null cycle for O₃). At low levels of nitrogen oxides (NO_x), IO self-reaction or reaction with BrO radicals (Cycle 1) and reaction of IO with hydroperoxy radicals (HO₂) (Cycle 2) dominate.

Cycle 1

Note that the IO self-reaction has several channels with the IO dimer-forming channel [4b] (~50%) and the OIO-forming channel [4a] (~40%) being dominant (Bloss et al., 2001; Harwood et al., 1997; Sander, 1986; Gómez Martín et al., 2007) at atmospheric pressure:

Experimental data and theoretical calculations indicate that the lifetime of the IO dimer against dissociation to I + OIO is around 1 s under atmospheric conditions, thus OIO is the main product of reactions [4a], [4b], and [4c] (Gómez Martín and Plane, 2009; Kaltsoyannis and Plane, 2008). As well as its self-reaction, IO can react with BrO in a cross reaction that produces OIO and Br (80%) and I + Br (20%) (Sander et al., 2006).

The photolysis rate and pathways of OIO are critical in determining its ozone destruction potential; only channel [5a] will result in net loss of O₃.

While measurements of the absorption cross sections of OIO have converged (Bloss et al., 2001; Gómez Martín et al., 2005; Joseph et al., 2005; Tucceri et al., 2006), the photolysis yields are still under debate. A number of experimental (Ingham et al., 2000; Cox et al., 1999; Joseph et al., 2005; Tucceri et al., 2006) and computational studies (Misra and Marshall, 1998) have all indicated a high photochemical stability for OIO and/or very low branching ratios for channel [5a]. However, high-resolution spectroscopy of OIO provided evidence for a very short-lived excited state (~200 fs) and indicated that channel [5a] dominates in the visible region (Ashworth et al., 2002). This is consistent with a recent experimental study, utilizing simultaneous measurements of OIO and atomic I (Gómez Martín et al., 2009), which determined an I atom quantum yield of unity from channel [5a]. This results in an atmospheric photolysis rate of $J(OIO) = 0.4 \text{ s}^{-1}$ at noon during summer solstice at 40° N (Saiz-Lopez et al., 2012) and indicates that OIO should be present at only very low levels during daytime. The available field data so far do not help to consolidate these laboratory studies. Daytime OIO observations have been reported in some cases (Stutz et al., GRL, 2007) while in others OIO is only seen at night (Peters et al., 2005; Mahajan et al., 2009) (see Section [Coastlines](#)). Rapid photolysis of OIO enhances the ozone-depleting potential of Cycle 1 but limits the potential role of OIO in new particle formation (see Section [Recycling of Iodine through Aerosol](#)).

Cycle 1 is believed to dominate O₃ destruction when relatively high mixing ratios of halogen oxides are present

(typically, more than 2 pptv of IO and BrO). At lower halogen oxide concentrations, reaction with HO₂ radicals (Cycle 2) becomes important:

Cycle 2

Note that while Cycle 2 is well understood, the reaction of IO with CH₃O₂ is uncertain both in terms of rate (differing by a factor of 30; Bale et al., 2005; Enami et al., 2006; Dillon et al., 2006, 2010) and in products, with potential channels representing both radical cycling and radical sinks. Bloss et al. (2010) showed that the range of rate constants/products for this reaction alone alters the predicted OH levels by up to 35% in the Antarctic boundary layer.

In semipolluted atmospheres, i.e., NO₂ > 1 ppbv, IONO₂ is a major gas-phase iodine species (Mahajan et al., 2009) and Cycle 3 can contribute to O₃ depletion.

Cycle 3

Photolysis of IONO₂ (which is much faster during the day than thermal dissociation; Kaltsoyannis and Plane, 2008; Saiz-Lopez et al., 2012) via channel [10] of Cycle 3 yields I atoms thus representing an O₃-depleting cycle. The NO₃ fragment produced, however, photolyses to form NO₂ + O with a branching ratio of 0.9 (Atkinson et al., 2009), leading to further ozone formation and reducing the overall O₃-depleting efficiency of this channel. Further, photolysis of the IONO₂ formed is in competition with its removal from the gas phase though uptake to aerosol, although the uptake coefficients and subsequent condensed phase chemistry of IONO₂ are highly uncertain.

In the presence of a few parts per billion of NO₂, models (von Glasow et al., 2002; Pechtl et al., 2006) have predicted very small levels of IO and OIO, with most IO_y converted to IONO₂. However, a number of recent field studies have shown that IO levels are essentially unaffected by several parts per billion of NO_x (Stutz et al., 2007; Whalley et al., 2007; Mahajan et al., 2009). Stutz et al. (2007) postulated that a fast recycling mechanism efficiently regenerates IO from IONO₂; this was later proposed by Mahajan et al. (2009) to occur via an autocatalytic reaction of IONO₂ with atomic I (reaction [13]), in accord with theory (Kaltsoyannis and Plane, 2008):

The I atoms produced from I₂ photolysis will react with IONO₂ rather than O₃ if the ratio [IONO₂]/[O₃] is >0.01 (Kaltsoyannis and Plane, 2008). These reactions thus represent an autocatalytic cycle that limits the build up of IONO₂ and maintain active iodine chemistry and consequent particle formation (see Section *Aerosol Formation and Iodine Oxide Particles*) even in a relatively high NO_x environment.

The forward reaction of I₂ with NO₃ radicals (reaction [13]) represents an additional IO production pathway at night. This reaction has been postulated as the source of nighttime IO observed at Mace Head in association with high NO₃ mixing ratios (Saiz-Lopez et al., 2006).

Recycling of Iodine through Aerosol

The net transfer of iodine from the gas to the condensed phase is reflected by the factor of 100- to 1000-fold enrichment of I in fine-fraction marine aerosol by comparison to the I/Na ratio in seawater (Duce and Hoffman, 1976; Sturges and Barrie, 1988; Baker et al., 2000). While aerosol then represents a net sink for iodine, the interaction of iodine with sea-salt aerosol can accelerate gaseous halogen release and provide a mechanism for maintaining gaseous iodine levels away from emission sources.

The first mechanisms proposed for the release of reactive halogens from aerosol required significant concentrations of nitrogen oxides (Finlayson-Pitts, 1983; Zetzsch et al., 1988). Vogt et al. (1996) suggested an autocatalytic cycle for bromide and chloride release in low NO_x environments and later (Vogt et al., 1999) proposed that the cycling of iodine in sea-salt aerosol could accelerate halogen release, mainly through acid-catalyzed aerosol scavenging of HOI, formed in Cycle 2:

Release of ICl and IBr after interaction of HOI on salt surfaces has been verified in laboratory experiments (Holmes et al., 2001; Mössinger and Cox, 2001) and is believed to significantly increase the gas-phase halogen reservoir (Vogt et al., 1999).

Similarly, the uptake of IONO₂ formed on sea-salt aerosol enhances the release of chlorine and bromine from sea-salt particles into the gas phase, which can then cause further O₃ depletion (McFiggans et al., 2002). Further, the uptake and hydrolysis of IONO₂ on aerosol is a potentially important removal pathway for NO_x in the remote troposphere (McFiggans et al., 2000), leading indirectly to increased rates of ozone destruction (Stutz et al., 1999). Thus, although the direct O₃-depleting potential of Cycle 3 is small (because NO₃ generated from channel [10] produces O₃), the indirect effects of enhanced halogen release from sea-salt aerosol and removal of atmospheric NO_x may be important in reducing boundary layer ozone concentrations.

Aerosol Formation and Iodine Oxide Particles

Bursts of ultrafine particle production events linked to low tide and solar radiation were first observed at the coastal site of Mace Head, Ireland (O'Dowd et al., 1998, 2002). Similar peaks in iodine-containing compounds at low tide (Alicke et al.,

1999; Carpenter et al., 1999, 2001) led to speculation as to the involvement of iodine in the particle formation mechanism. Analysis of new ultrafine particles at Mace Head confirmed that iodine is an important component (Mäkelä et al., 2002) and numerous laboratory investigations have shown that in the presence of ozone, photodissociation of iodine precursors leads to rapid new particle formation composed mainly of iodine oxide particles (IOPs) (Burkholder et al., 2004; Cox and Coker, 1983; Cox et al., 1999; Hoffmann et al., 2001; Jimenez et al., 2003; Saunders and Plane, 2005, 2006; Saunders et al., 2010). IOPs could provide condensation nuclei for other condensable vapors and grow to the point of becoming cloud condensation nuclei (CCN), which would impact on the radiative balance of the atmosphere and hence on climate (Burkholder et al., 2004; Hoffmann et al., 2001; Jimenez et al., 2003; O'Dowd et al., 1998, 2002a; McFiggans et al., 2010).

Although strong links between iodine, new particles, and particle growth in the coastal MBL have now been established, the chemistry of the particle-forming higher oxides of iodine is still poorly understood. IOPs are thought to be initiated by the release of I_2 from kelps (see Section [Coastlines](#)) and consequent formation of IO, followed by recombination reactions of IO and OIO (formed from the IO self-reaction and $IO + BrO$ cross reactions) to form higher oxides (Gómez Martín et al., 2007):

Theoretical work indicates that I_2O_3 is stable at MBL temperatures (Kaltsoyannis and Plane, 2008), but there is little quantitative information on the higher iodine oxides. As discussed earlier, recent work suggests a short photolysis lifetime for OIO, increasing the ozone depletion potential but decreasing the potential for IOP formation.

Solid IOPs are mostly likely comprised of I_2O_4 and I_2O_5 (Saunders and Plane, 2005; Saunders et al., 2010). Saunders and Plane (2005) speculated that the oxidation of I_2O_4 by O_3 was responsible for production of gas-phase I_2O_5 , which then polymerized to produce IOPs. However, a more recent study (Saunders et al., 2010), utilizing N_2O photolysis to form O atoms and hence IO by reaction with I_2 , has demonstrated that IOPs can form in the absence of O_3 and are thus most likely initiated by the spontaneous polymerization of I_2O_3 and I_2O_4 , formed in reactions [16] and [17]. The dry particles are believed to restructure in the solid phase to I_2O_5 and I_2 . In humid marine environments, the IOPs are likely to hydrolyze to HIO_3 (iodate) (Saiz-Lopez et al., 2012).

Once IOPs form, they will only have an impact on climate if they grow to a sufficient size to either scatter and absorb solar radiation (direct impact) or to enhance CCN concentrations (indirect impact). Even in coastal environments with high macroalgal I_2 emissions, the supply of iodine oxides is likely to be limited, thus the IOPs will only grow by condensation of other vapor species such as water, sulfuric acid, or ammonia. In fact, the accommodation of H_2SO_4 vapor on IOP has recently been shown to be very efficient, particularly at high relative humidities (Saunders et al., 2010). In the coastal MBL, uptake of H_2SO_4 onto IOPs is likely to be accompanied by H_2O and NH_3 (Kulmala and Kerminen, 2008; Kulmala et al., 2002; O'Dowd and De Leeuw, 2007). So far, it is not established

whether particles originating from IOPs can act efficiently as CCN at realistic marine supersaturations nor whether, if this does occur, that the regions affected are sufficiently large to induce significant radiative impacts.

Radioactive Iodine

Radioactive isotopes of iodine are produced in fission of uranium and plutonium. Radioactive iodine can be inhaled as a gas or ingested in food or water and is of concern for human health, with a direct link to thyroid cancer. Radioactive I-131 (I-131; half-life 8.02 days) is assumed to cause the majority of the excess thyroid cancers seen after bomb fallout and severe nuclear reactor accidents. Children are at greater risk from radioactive iodine exposure than adults, and thyroid cancers attributed to I-131 exposure during childhood continue to occur throughout adulthood (Brenner et al., 2011). The accident at the Chernobyl nuclear power plant in 1986 was the most severe in the history of the nuclear power industry, releasing huge quantities of radionuclides over large areas of Belarus, Ukraine, and the Russian Federation and causing several thousand cases of thyroid cancer (Williams, 2008). The release of radioactive material to the atmosphere following the Japanese Fukushima nuclear accident on 11 March 2011 has been estimated to be approximately 10% of the Chernobyl accident (International Atomic Energy Agency). Contamination of the marine environment occurred through atmospheric fallout or washout with precipitation and through discharges of contaminated water into the sea.

Iodine-129 (I-129; half-life 15.7 million years), mainly released in the past from above-ground nuclear testing and now from nuclear reprocessing facilities, is one of the most persistent radionuclides, and can participate in the biogeochemical cycling of iodine, as well as potentially accumulating in human thyroid glands (Hou et al., 2000). Historical and ongoing release of I-129 has caused a significant increase of this isotope since the prenuclear era within the ocean mixed layer, rivers, and lakes (Reithmeier et al., 2005, 2010), in marine sediments (Fehn et al., 1986; Lopez-Gutierrez et al., 2004), in glacier ice (Wagner et al., 1996; Reithmeier et al., 2006), and in moss (Sumerling, 1984; Rucklidge et al., 1994). In Europe, the majority of I-129 is currently released in liquid form from the reprocessing facilities at La Hague (France) and Sellafield (UK) (Hou et al., 2007; Reithmeier et al., 2005, 2010) to the Irish Sea and to the English Channel where it is present mostly in the oceans' upper water layer (Reithmeier et al., 2010). Chemical speciation of I-129 in the ocean is mainly as iodide and iodate, although the iodide/iodate ratio for I-129 appears to be higher than that for the natural isotope I-127 (Hou et al., 2007). Although the annual reemission rate of I-129 from the ocean to the atmosphere is reported to be less than about 0.3% of its load in the upper layer of the ocean, this contribution is comparable to that of the combined gaseous release from La Hague and Sellafield (Reithmeier et al., 2006). I-129 originating from gaseous release from reprocessing facilities, and from the fraction of I-129 that escapes the oceans' surface water, is primarily deposited by rain and, to a much smaller amount, by dry deposition (Lopez-Gutierrez et al., 2001). Although the current environmental levels of I-129 do not

present a significant radiation risk for human health, continued release at the present level could present a long-term radiological risk (Hou et al., 2000).

Introduction

Away from the surface the atmosphere is mainly statically stable with little small-scale turbulent mixing occurring outside frontal regions, areas with moist convective updrafts, and regions with breaking gravity waves generated by hills and mountains. In contrast, adjacent to the surface the flow is nearly always turbulent, with the turbulence generated by the action of wind shear and/or buoyant convection. This layer adjacent to the surface in which vertical mixing is especially important is termed the boundary layer. In fact, turbulent boundary layers involving shear or buoyancy effects are a key feature of all bounded fluid flows at high Reynolds number. However, the atmospheric boundary layer involves a variety of features and processes in addition to shear and buoyancy. For example, there is often a distinct interface at the height where the mixing reaches the base of the stable free atmosphere above. Other dynamical and thermodynamical processes that affect the atmospheric boundary layer are Coriolis forces produced by the planetary rotation, and factors such as the formation of clouds and radiative heat transfer.

The ocean is also mainly statically stable and has boundary layers at its top and bottom. The boundary layer at the bottom of the ocean, which is generally much thinner than the atmospheric boundary layer, is called the benthic boundary layer. Here fluxes of heat and buoyancy influences are weak and the boundary layer is usually shear-driven. The surface of the oceans, in contrast, can have substantial fluxes of buoyancy as well as significant shear arising from the influence of the wind at the surface.

The term boundary layer is also sometimes used in association with flows and currents that are concentrated against the sides of basins or orography. These features, such as the Gulf Stream in the North Atlantic Ocean, arise from the flow dynamics without mixing playing a critical role. They are not discussed further here.

Role in the Overall Atmosphere

The boundary layer has an important influence on the behavior of the atmosphere as a whole, and activities involving the representation of the atmosphere such as climate modeling and numerical weather prediction cannot

succeed without the boundary layer being represented in some detail. The main influences on the atmosphere as a whole are as follow:

- Over level terrain the boundary layer determines the drag between the atmosphere and the surface and this drag is the main mechanism by which the energy in the large-scale motion is dissipated. With small-scale orography the drag also occurs through pressure forces whose magnitude is influenced by the boundary layer turbulence.
- It provides a buffer between the surface and the atmosphere, thus influencing the transfer of heat and moisture between the surface and the atmosphere and, in particular, the way surface solar heating is partitioned into sensible and latent heat fluxes.
- It is critical in determining the properties of air entering the base of clouds that form the roots for moist convection extending into the atmosphere above the boundary layer.
- It plays a central role in determining the occurrence of low-level cloud within the boundary layer and the consequential effects on radiation budgets.
- It tends to retain aerosols and pollutants from the surface, with the transfer of such polluted air to the free troposphere being limited mainly to moist convection and frontal motions which, through washout, leave the main atmospheric air free of such material.

Role in the Local Atmospheric Environment

The boundary layer is of particular significance to human activities and natural processes occurring on the Earth's surface. Here prediction and understanding of the local environment requires an understanding of the boundary layer. In particular, the boundary layer is important for predicting a range of parameters such as

- the near surface wind and turbulence;
- daily maximum and minimum temperatures;
- visibility and fog;
- the dispersion of pollutants and other material.

Role in the Oceans

As in the atmosphere, boundary layers in the oceans play an important part in the overall and local ocean circulations:

- In the deep ocean, the bottom benthic boundary layer has only a weak dissipating influence on the ocean circulation, although it plays a more important role on the continental shelf and in coastal regions.
- The surface boundary layer plays a key role in influencing the rate of exchange of heat and momentum between the atmosphere and the ocean and is consequently critical to the ocean circulation.

Theoretical Framework

In turbulent flow, the fluxes of flow variables are caused by the differing properties of air 'parcels' moving in different

directions relative to the mean flow (the mean flow usually being defined, from a practical perspective, as an average over a period of order an hour). For example, if the rising air parcels are warmer than those descending, then there will be a vertical flux of heat H . This heat flux H is equal to $\rho c_p \langle w'T' \rangle$, where ρ and c_p are the density and specific heat capacity of air and $\langle w'T' \rangle$ is the covariance of w' and T' , the turbulent fluctuations in vertical velocity and in temperature about their means. Similarly, the covariance between the horizontal and vertical velocities gives rise to a downward vertical flux of horizontal momentum τ which is given by $-\rho \langle u'w' \rangle$, where u' is the fluctuation in the horizontal component of velocity. Such a momentum flux is often referred to as a turbulent stress.

These turbulent fluxes have a major effect on the flow. For example, if we consider the average flow in a horizontally homogeneous boundary layer over an area of the earth surface, the governing equation of the horizontal momentum balance is given by eqn [1].

$$\frac{d\mathbf{U}}{dt} = -\frac{1}{\rho} \text{grad } p - f\mathbf{k} \times \mathbf{U} + \frac{1}{\rho} \frac{d\tau}{dz} \quad [1]$$

Here p is the mean pressure, f is the Coriolis parameter, $\mathbf{k}$ is a unit vertical vector, $\mathbf{U}$ is the (horizontal) mean velocity vector, and z the vertical coordinate, with the adjective 'mean' being used to indicate quantities where the turbulent fluctuations have been averaged out. Above the boundary layer where τ is zero, the flow will tend to adjust to a steady state with a balance between the pressure and Coriolis forces, leading to a geostrophic flow at right angles to the pressure gradient. Within the boundary layer, however, there is a rotation of the flow away from the geostrophic direction, with the wind having a component directed down the pressure gradient. Similar equations can be written for other variables such as temperature or humidity. These equations will contain a balance between the rate of change and the flux gradient, together with any source terms such as – in the case of the temperature equation – the radiative transfer divergence.

Field experiments have yielded many useful data on flow covariances such as $\langle u'w' \rangle$. In a theoretical description the key issue is to estimate the covariance from the flow properties. This is an impossible problem to resolve fully, because the flow eddies determining the flux evolve through complex, nonlinear and turbulent interactions, making it intractable to obtain exact solutions for the fluxes in terms of the mean flow variables. In many cases, however, progress is possible through simple closure approximations (which relate the turbulence statistics to the local mean flow) and/or through consideration of bulk models.

The simplest closure method is the eddy-viscosity approach in which the flux is assumed proportional to local mean gradients through a turbulent 'eddy viscosity' or 'eddy diffusivity', in the same way as fluxes due to molecular motions are related to gradients via molecular viscosities and diffusivities. In the case of the velocity covariance in the momentum balance equation, this leads to the approximation of eqn [2].

$$-\langle u'w' \rangle = K \frac{dU}{dz} \quad [2]$$

K is the eddy viscosity, which varies in space and time. K itself is usually determined by a combination of dimensional

considerations and empirical measurements. It can usefully be thought of as a turbulent velocity scale multiplied by a length scale, by analogy with the way molecular mixing is related to the size of molecular velocities and the length of the mean free path. Close to the surface, dimensional considerations imply a dependency on the distance from the surface (physically this is because eddy sizes are restricted by the presence of the ground and so tend to be smaller close to the ground) while toward the middle of the boundary layer some length scale related to the boundary layer depth will prevail. A separate estimate of velocity scale is needed. This may be obtained from local or bulk considerations. A local determination can be made by considering a mixing length model (see below) or by considering the turbulence energy equation with consideration of both shear and buoyancy effects.

Although eddy viscosity approaches and other closure models are only an approximate representation of the turbulence properties, under appropriate conditions model-independent results can be derived through dimensional considerations combined with an empirical determination of dimensionless constants or functions. Such similarity descriptions have extensive application in a region near the ground where the flow depends on only a few variables. This region, called the surface layer, occupies the part of the flow where the height z is much greater than the roughness elements but much less than the depth of the boundary layer. The structure of the flow in this region is thought to be characterized by a few parameters, namely, the friction velocity u_* (defined as $\sqrt{(\tau/\rho)}$ where τ is the magnitude of the surface stress), the surface flux of sensible heat H , and the height z above the surface. In neutral stability conditions, with $H = 0$, dimensional analysis then leads to eqn [3].

$$\frac{dU}{dz} = \frac{u_*}{kz} \quad [3]$$

k is the von Karman constant (which has an empirically determined value of about 0.4) and U is the magnitude of the mean wind. Integrating this equation leads to the log law (eqn [4]).

$$U = \frac{u_*}{k} \log \frac{z}{z_0} \quad [4]$$

Here z_0 , the constant of integration, is related to the height of the roughness elements and is called the roughness length. It is typically about one-tenth of the actual height of the roughness elements.

The eddy viscosity approach can provide an exact match to these similarity relations if appropriate empirical choices for the coefficients and the various scales are used. As a simple illustration, consider the situation in the surface layer for the case of neutral stability. Here we can write eqn [5], where l_0 and u_0 are the length and velocity scale determining the eddy viscosity K .

$$\langle u'w' \rangle = K \frac{dU}{dz} = l_0 u_0 \frac{dU}{dz} \quad [5]$$

To match the similarity relation [3], we can choose $u_0 = u_*$ with l_0 equal to kz . If we also note that $\langle u'w' \rangle$ varies only slowly within the surface layer (the surface layer is often as a result referred to as the constant-stress layer) and that it can be approximated by the surface stress u_*^2 , then we again obtain the

log law. The choice of u_* as the correct velocity scale can be difficult to understand (both here and in the pure similarity approach above) and one way to motivate this is to consider a mixing length model. We assume air is mixed in the vertical over a length scale l_0 (the mixing length) and assume that the air starts off with the local mean horizontal velocity and retains this velocity as it travels. At the end of its journey it has a horizontal velocity that differs from the local mean by $u' \sim l_0(dU/dz)$. Taking this as our velocity scale u_0 we obtain eqn [6].

$$u_*^2 = \langle u'w' \rangle = l_0 \left(l_0 \left| \frac{dU}{dz} \right| \right) \frac{dU}{dz} = (kz)^2 \left| \frac{dU}{dz} \right| \frac{dU}{dz} \quad [6]$$

These surface relations can be refined to incorporate buoyancy effects. From dimensional considerations, the velocity scale w_f at a height scale z due to a heat flux H is given by eqn [7].

$$w_f^3 = \frac{kgHz}{\rho c_p T} \quad [7]$$

This order of magnitude estimate of the local buoyancy-driven velocity scale could have been more physically derived by considering the energy equation or buoyancy accelerations subject to the key recognition of distance from the surface as the relevant length scale. From similar dynamical considerations, we can derive an important length scale, the Monin–Obukhov length L , which is the height scale at which the shear and buoyancy velocity scales are equal. It is defined by eqn [8].

$$L = \frac{-zu_*^3}{w_f^2} \quad [8]$$

This is a key parameter in the surface layer, and z/L is a measure of the relative role of shear and buoyancy in the production of turbulence. The flow in the surface layer is then determined by eqn [9].

$$\frac{dU}{dz} = \frac{u_*}{kz} \varphi_M \left(\frac{z}{L} \right) \quad [9]$$

Here φ_M is an empirical function which has been estimated experimentally. Similar relations hold for other variables, and by integration stability-dependent bulk formulas can also be obtained. φ_M is greater than unity in stably stratified conditions ($L > 0$) where turbulence transfer is weaker (i.e. for fixed dU/dz the momentum flux is reduced) and less than unity in convective conditions ($L < 0$). At heights much less than $|L|$, buoyancy effects are unimportant and $\varphi_M \sim 1$, with U approaching the log law appropriate for neutral conditions.

In a model of the boundary layer, the net impacts can be described by bulk drag and transfer coefficients that relate the surface stress to the wind U at some finite height via eqn [10].

$$\tau = C_D |U| U \quad [10]$$

It is trivial to relate this bulk formula to the similarity result – for example, in neutral conditions C_D is given by $C_D = (k/\log(z/z_0))^2$.

Although the classical surface layer theory outlined above has proved to be one of the cornerstones of boundary layer theory, it is important to realize that it may not be exactly correct. For example, the presence of large eddies that fill the boundary layer will cause horizontal fluctuations in wind

near the ground whose properties depend on the boundary layer depth. This is particularly true in convective conditions, but may also play a role in other types of boundary layer.

Types of Boundary Layer

In both the atmosphere and the oceans, boundary layers occur in forms that can be complex, involving a diverse mixture of processes and space and time dependencies. In spite of this general complexity, boundary layer properties can often be understood in terms of the properties of a number of idealized cases, and these cases provide an overview of the range of possible behavior. The simplest cases are those with horizontally homogeneous and steady conditions, and these are best classified by stability.

In the neutral boundary layer, where the surface heat flux is negligible, the wind increases steadily with height (although at a decreasing rate) and the wind direction varies throughout the boundary layer. Such neutral conditions, where shear flow turbulence generation dominates, occur as often because the wind speed is large because the heat flux is actually close to zero. The relevant criterion is that the boundary layer depth is smaller than the magnitude of the Monin–Obukhov length L . Turbulence levels scale on the friction velocity u_* and decrease steadily with height. With a geostrophic wind speed of 10 m s^{-1} , typical values of u_* and of fluctuations in wind speed are about 0.3 m s^{-1} and 1 m s^{-1} respectively, depending of course on the surface roughness. If there are no thermal effects at all, then the boundary layer depth is of order $0.3u_*/f$. However, the term neutral boundary layer usually refers only to the absence of a heat flux at the surface, and stratification and subsidence above the boundary layer almost invariably play an important role in restricting the actual boundary layer depth.

In convective boundary layers the surface heating is sufficient to make the Monin–Obukhov length very much less than the boundary layer depth. The vertical mixing is stronger and this tends to produce nearly uniform profiles of velocity and temperature, with variations largely confined to near the surface and the boundary layer top. With heat being continually added at the surface, a completely steady situation is impossible and the boundary layer usually grows slowly as the stable stratification above the boundary layer is eroded. The nature of this erosion often acts to sharpen gradients at the boundary layer top and frequently there is a strong temperature inversion extending over only a few tens of meters. Vertical turbulent velocities tend to peak some way above the ground (at about a height of $d/3$ where d is the boundary layer depth), with lower values near the ground and boundary layer top. Horizontal turbulent velocities, however, are more uniform as these are not blocked by the presence of the ground. The typical velocity scale is linked to the boundary layer depth and is of order the convective velocity scale w^* which is given by eqn [11].

$$w_*^3 = \frac{kgHd}{\rho c_p T} \quad [11]$$

A typical value for the daytime convective boundary layer in mid-latitudes is about 1 or 2 m s^{-1} . The largest eddies extend

throughout the depth of the boundary layer. In summer in mid-latitudes with clear skies, convective boundary layers will reach a depth of order 2 km by late afternoon. Pollutants emitted into convective boundary layers are dispersed rapidly. This leads to small ground level concentrations from near-surface emissions. However, convective conditions can lead to high near-surface concentrations from releases from elevated stacks because the rapid mixing can bring material down to the ground quickly before it has been much diluted. In these conditions plumes are often seen to ‘loop’ up and down as they are distorted by boundary layer eddies that are much larger than the plume.

In stable boundary layers that generally occur at night or over other cool surfaces, mixing is greatly reduced and temperature and wind vary across the whole depth of the boundary layer at a more constant rate than in neutral conditions. Three-dimensional turbulent eddies tend to be smaller than in the neutral or convective cases and turbulence levels tend to be low (although they scale with u_* as in the neutral case, u_* itself tending to be smaller in stable cases). In addition to the three-dimensional turbulence, slow lateral meandering motions are often present. Stable boundary layers tend to be much shallower than convective or neutral boundary layers, with a typical depth of order 100 – 200 m . Often, however, wind shear is present above the true stable boundary layer due to the legacy from the daytime boundary layer and/or inertial oscillations. In very stable cases it seems that the turbulence can be completely suppressed at times and becomes intermittent. This regime is very hard to understand and predict because small influences that have a negligible effect on neutral and convective boundary layers can become important – examples are slight slopes, variations in the thermal properties of the ground, and spatial variations in cloud cover. Pollutants emitted into stable boundary layers are dispersed slowly. This can lead to high ground level concentrations for near-surface sources. However, ground level concentrations from elevated sources can be small because the plume is mixed down to the ground only very slowly, and may be released at such a height or with sufficient buoyancy that it is carried completely above the boundary layer. Typical profiles of wind and temperature for neutral, convective, and stable boundary layers are shown in Figure 1.

In the real atmosphere, conditions always vary with time, but usually the time variation is slow enough for the main characteristics of the ideal boundary layers to prevail. A primary cause of variation over land is the diurnal cycle. The boundary layer starts at night with a shallow, stable layer. As the sun rises and heats the ground, convective turbulence is generated and a convective boundary layer is formed that gradually erodes the stable layer above the boundary layer to reach its maximum depth by late afternoon. Then the sun sets and the ground starts to cool, with thermal effects now tending to suppress the turbulence. As a result, the turbulence decays rapidly except in a shallow layer near the ground, which forms a new stable boundary layer. Although this is a useful idealized description, it should be noted that there are many situations in which it does not apply. For example, in strong winds, the ‘mechanical’ effects may dominate the thermal effects in the boundary layer energy balance, leading to an effectively neutral boundary layer. Also, at high latitudes the sun may not be strong enough

Figure 1 Illustration of typical profiles of mean wind (U , V) and potential temperature (θ) in neutral, convective, and stable atmospheric boundary layers, for a geostrophic wind of 10 m s^{-1} and a surface temperature of 20°C . The dashed lines indicate the boundary layer top, which is generally well defined only in the convective case. The profiles are based on the results of large-eddy simulations for idealized conditions but, for reasons of illustration, have been adjusted to indicate the typical relative depths of the three types of boundary layer. Real profiles will show significant differences due to a range of influences and to the presence of turbulent fluctuations that will not be completely removed even if the profiles are averaged over a period of an hour.

to make H positive. Over the sea the diurnal cycle is almost absent owing to the greater heat capacity of the sea and hence the smaller changes in surface temperature.

In this short introduction it is especially difficult to do justice to the full range of complexities that can have some influence upon the boundary layer, but we can note some key ones. Clouds and fog within the boundary layer do not release enough rain or drizzle to be significant net sources of latent heating but rather have influence through acting to redistribute heat and moisture within their circulations and through the effect of radiative cooling on the cloud tops. Such cooling can be the main source of turbulence energy production in situations with fog and stratocumulus-capped boundary layers. Entrainment is a key process in the heat and moisture budgets of such boundary layers, and the development of cloudy boundary layers is sensitive to this and the surface fluxes. The entrainment can be driven by the action of the boundary layer eddies and is also influenced by wind shear and the potential for dry entrained air to give evaporative cooling of the cloud.

The matching of the description of the turbulent flow to the surface properties is a key issue because the surface fluxes are critical to the overall boundary layer properties. At the surface a great range of complex issues prevail as the flow interacts with the obstacles and vegetation that comprise the surface. The availability of empirical data is usually essential to quantitative prediction. Over homogeneous surfaces with level terrain we have noted that the momentum transfer properties of the surface can be represented by the roughness length z_0 . Corresponding roughness lengths can also be used for heat and moisture and they are generally much smaller because scalar fluxes do not involve pressure forces. They are also less accurate in use owing to variations with plant properties as they interact with varying soil moisture, humidity, temperature, and

radiative fluxes. It is common in models to refine the treatment of vegetated surfaces with plant canopy models that seek to represent key processes such as those of the plant stomata, and even flow within the plant canopy.

The task of representing the surface is made more difficult by the presence of heterogeneity in the surface. The boundary layer tends to respond to an area average of the surface properties. This is somewhat the inverse of the way in which a pollutant from a point source would occupy a large area at heights some distance above the surface. The methods of forming area average properties involve consideration of boundary layer dynamics. Orography on a scale of several kilometers or less is another important surface feature. The consequent pressure forces on the flow give a large surface drag with high levels of turbulence and mixing.

Over the sea it is usual to use either roughness lengths or the equivalent bulk transfer relations. The values are not constant but are mainly functions of wind speed. The momentum transfer occurs mainly through pressure forces on the waves and varies with wind speed as a result of its influence on the wave height. The values of roughness length are generally smaller than over land surfaces. The scalar transfer coefficients increase only weakly with wind speed and spray generation may be one cause of this. For waves in equilibrium with the wind there are reasonable empirical descriptions of the transfer coefficients. More refined approaches seek to use wave models to allow for the waves being out of equilibrium with the wind. There also remains uncertainty over transfer in very strong wind conditions when severe spray makes measurements impossible. These surface fluxes match into the oceanic surface boundary layer, which also receives the influence of any radiative transfer and input of fresh water from precipitation. The oceanic surface boundary layer is subject to dynamics

comparable with those of the basic neutral, stable, and convective atmospheric boundary layers. However, the time scales for the variations in the mean structure of the temperature and salinity profiles differ and derive from a combination of the seasonal heating and cooling modulated by the daily weather cycles. The main areas of the ocean have a stable thermocline somewhat analogous to the stable cap of most atmospheric boundary layers. Deep penetrating convective motion tends to occur in more limited areas where strong cooling occurs. In the atmosphere, vertical movement of air through a significant fraction of the depth of the troposphere is similarly restricted in its area, but the areas of occurrence are linked to moist convection in deep cumulus clouds or frontal zones and not directly to persistent heating.

Practical Boundary Layer Models PBL

Models of a variety of types are used to represent and predict boundary layers. Even the simplest work well in some cases, while even the most complex is not able to give reliable results in all circumstances. Fortunately we have a fair understanding of the reasons for success and failure and can at least anticipate these.

The simplest of these models are 'bulk' models that estimate, for example, the drag and the boundary layer depth directly from the external parameters such as the wind above the boundary layer and the roughness length. More sophisticated models attempt to estimate the various fluxes that occur in the equations for the mean boundary layer properties. This is done either directly and locally within the flow in terms of the mean quantities (mixing length models are the main example here) or by deriving equations for the fluxes and then attempting to estimate the unclosed terms in those equations. The full equations for the fluxes can be simply derived from the equations of motion. Just as in the averaged equations of motion, where a closure model is required for the fluxes, so in these new equations a closure is needed for the higher-order terms that appear. The terms requiring closure involve triple moments and correlations of velocity and pressure. In a so-called second-order closure, a closure assumption is made for these terms. Generally this closure is, as in mixing length models, in terms of local flow properties. Such models usually only address the very difficult issue of nonlocal influences through a more questionable derivation of the local turbulence length scale and through diffusion of the second-order quantities. Typically, in situations where mixinglength models are reasonable, higher-order closure models will do better, and are quite successful in capturing the extra flow details. Neither model can usually deal at all well with the details of flows such as convective ones with strong nonlocal influences. Higher-order closures such as third-order ones have shown success in some cases but they seem unreliable when applied over a wide range of flows.

More sophisticated again are large-eddy simulation (LES) models. These models attempt to simulate the detailed evolution of the flow eddies within the boundary layer, although of course, because the smallest structures have a size of order 10^{-3} m, it is impossible to describe the entire flow in detail. Instead, the largest eddies are simulated, with the effects of the smallest scales parametrized (e.g., with a mixing length model).

The hope and evidence are that results will be insensitive to the treatment of these small scales and so results will not be compromised by errors in the parametrization. In using the LES technique it is not expected that the instantaneous details of the flow will correspond to a particular real case. Instead, the model results are used to derive mean quantities which, by averaging out the unpredictable turbulent variability, should be comparable with reality. In this sense the model is used more in the way climate modelers use large-scale meteorological models than in the way weather forecasters use them. The results from LES show great promise for the future and with adequate numerical resolution they offer a basis both to make direct predictions and to provide flow details with which to develop other closure methods. It can be argued that in the interior of the boundary layer little more is needed from the subgrid parametrization than to allow dissipation to occur explicitly at the smallest resolved scales. The only particular difficulty with LES is that it depends on achieving a correct parameterization near the surface. At the surface the flow eddies become too small for the LES to describe them explicitly. The LES solutions depend upon the closure in this region and in the transition from this region to the flow interior where the resolved eddies dominate the flow.

Models for predicting the dispersion of material in the boundary layer also have a similar range of degrees of sophistication. The simplest models estimate the width of any plume spread directly from a few parameters, e.g., wind speed, time of day and year (to estimate the solar elevation), and cloud cover (which affects the surface radiation budget). Some models involve mixing-length type assumptions or higher-order closure models. For a dispersing plume, the horizontal variations are critical as well as the vertical ones and so, unlike boundary layer models that are often one-dimensional, a fully three-dimensional description is required. A more sophisticated approach is to simulate the motion of many elements of the pollutant in a 'stochastic Lagrangian particle' model. Here the statistical properties of the flow (e.g. mean flow and velocity variances and covariances) are assumed known and a stochastic model for the random dispersion of pollutant 'particles' is constructed to be consistent with these flow statistics. Finally, the LES technique described above can be applied to calculate dispersion as well as the mean flow and turbulence, either by tracking particles within the LES flow or by solving an equation for the evolution of the concentration field.

Summary and Challenges

Our understanding of the boundary layer has progressed greatly over recent decades. Much still remains to be done, however, and progress will depend critically on the development of theory, numerical computations, and the continuing refinement of empirical data. As theory and numerical computations gain in potential it will remain essential to ensure that the underpinning empirical factors that are so critical in turbulence continue to receive good attention.

Synopsis

Meteorological conditions play important roles in modulating the ambient concentrations of pollutants through different ways. For example, meteorological variables exert important influences on the formation and fate of pollutants such as ozone and aerosols; meteorological processes (e.g., advection and vertical mixing) dictate the dispersion of pollutants. Thus, accurately simulating meteorological conditions is critical for correctly simulating pollution events. Uncertainties are associated with model treatments for various processes in air quality models. Methods such as ensemble simulation and parameter estimation could potentially improve air quality simulations.

Description of Pollutants in the Air

The United States Environmental Protection Agency (U.S. EPA) set National Ambient Air Quality Standards (NAAQS) for six principal pollutants in 1990s to provide protection for public health and the environment. These six principal pollutants are called 'criteria' pollutants, which include carbon monoxide (CO), lead, nitrogen dioxide (NO₂), ozone (O₃), sulfur dioxide (SO₂), and particles (or aerosols). The NAAQS are periodically reviewed and revised to be in line with the updated science. Among the six criteria air pollutants, the formation of O₃ and aerosols involves the most complicated processes. Ozone is a secondary pollutant, produced from oxides of nitrogen and reactive organic gases in the presence of sunlight. When O₃ reaches critical levels, adverse environmental effects are expected for human health, crops, and natural vegetation. The adverse environmental effects of O₃ were first reported in Los Angeles during 1940s. Now it is realized that O₃ pollution is no longer confined to Los Angeles and it affects major urban locations in the world. Elevated O₃ concentrations were also reported in rural and even remote regions. Aerosols range from nanometers to hundreds of micrometers (μm), coming from both primary and secondary sources. Elevated concentrations of aerosols can cause or enhance respiratory, cardiovascular, infectious, and allergic diseases. The primary parameters that determine the environmental and health effects of aerosols are their concentration, size, structure, and chemical composition, which are spatially and temporally highly variable. The formation and fate of O₃ and aerosols have received extensive attention by the research community.

Structure of the Atmospheric Boundary Layer and Its Relationship with Plume Behaviors

The atmospheric boundary layer is defined as the lowest part of the troposphere that is directly influenced by the presence of the earth's surface, and responds to surface forcing within a timescale of about an hour or less. The variation of the boundary layer plays a critical role for dictating the dispersion of pollutants since most pollutants are emitted or formed in the boundary layer. The boundary layer depth may vary from hundreds of meters to a few kilometers. Over oceans, the

boundary layer depth varies relatively slowly in space and time due to little change of ocean water temperature. The boundary layer depth varies dramatically over the land. During the daytime, due to the surface heating from shortwave radiation, turbulence is generated in the lower 1–2 km above the ground, which is called the mixed layer. The turbulence tends to mix heat, momentum, moisture, and pollutants uniformly in the mixed layer. A stable layer at the top of the mixed layer restrains the vertical extent of turbulence. This layer is called the entrainment zone because entrainment into the mixed layer occurs at this layer. After sunset, turbulence decays in the formerly mixed layer. The upper portion of the formerly mixed layer becomes the residual layer, in which the state variables and concentrations of pollutants remain mostly invariant. The lower portion of the formerly mixed layer is transformed into a stable boundary layer, which is characterized by statically stable air with weaker, sporadic turbulence. After sunrise of the following day, the mixed layer starts to grow again.

A large portion of anthropogenic emissions is released in the form of plumes. Due to higher temperatures compared with the ambient air, these plumes are typically highly buoyant. Depending on the thermal conditions of plume itself and the ambient atmosphere, the plumes can rise to different heights. Different characteristics of the atmospheric boundary layer dictate the way the plumes are dispersed. Plumes released in the mixed layer may loop up and down initially and become uniformly distributed vertically eventually. Plumes released in the stable boundary layer fan out in the horizontal with little vertical dispersion. Plumes in the residual layer spread with an almost equal rate in the vertical and horizontal, exhibiting a conelike shape.

Tropospheric O₃ Chemistry and Aerosol Processes

The overall tropospheric photochemical O₃ formation mechanism is well known. In the troposphere, O₃ is produced from the photolysis of nitrogen dioxide ([R1]) and the subsequent reaction of the ground state oxygen atoms, O(³P), with molecular oxygen ([R2]).

Figure 1 Mean diurnal variation of O_3 and its standard deviation in Beltsville, Maryland, United States, during August 2010.

Once formed, O_3 may be removed from the atmosphere through dry deposition process and NO titration reaction [R3].

Ozone has different variability in different regions. In the continental atmospheric boundary layer, where the concentration of nitrogen oxides (NO_x) is relatively high, local photochemical production of O_3 will contribute to the O_3 maximum in the afternoon in the presence of sunlight and high temperature. Figure 1 shows the diurnal variation of O_3 in Beltsville, Maryland, United States, during August 2010. During the night, O_3 mixing ratios decreased due to NO titration ([R3]) and dry deposition. Photochemical reactions contributed to the O_3 formation during daytime. In the marine boundary layer, where the concentration of NO_x is relatively low, air chemistry can lead to the destruction of O_3 . Figure 2 shows the diurnal variation of O_3 mixing ratio at Kwajalein Atoll situated in the equatorial Pacific Ocean in summer 1999. During the daytime, O_3 photolysis, hydroperoxyl radicals (HO_2), hydroxyl radicals (OH), and bromine atoms (Br) contributed to the destruction of O_3 , which led to the observed minimum O_3 levels in the afternoon. The entrainment of O_3 -rich air from the free troposphere to the local marine boundary layer provided a recovery mechanism of surface O_3 during nighttime.

Aerosol particles are ubiquitous in the atmosphere with diameters ranging from a few nanometers to around hundred micrometers. The ambient aerosol particles are characterized by two modes, the fine mode (with a diameter $\leq 2.5 \mu m$) and the coarse mode (with a diameter $> 2.5 \mu m$). Fine mode aerosol particulate mass is referred to as $PM_{2.5}$, which is believed to pose the largest health risks. The aerosol particulate matter may

Figure 2 Mean diurnal variation of O_3 mixing ratio and its standard deviation at Kwajalein during July, August, and September 1999.

be either directly emitted or formed in the atmosphere, which are referred to as primary and secondary sources, respectively. Primary sources of aerosol include combustion, windblown dust, pollen, plant fragments, and sea salt. Secondary aerosols are produced in the atmosphere by photochemical processes and added to the preexisting particles through the gas/particle mass transfer process. Most of the mass of $PM_{2.5}$ is composed of secondary aerosol. In some cases more than 90% of the $PM_{2.5}$ mass may be attributed to secondary aerosol.

Effects of Meteorology on Air Pollution

Effects of Meteorology on Biogenic Emissions

Biogenic emissions play an important role in regional air quality and global atmospheric chemistry. Isoprene (C_5H_8) is the predominant volatile organic compound (VOC) emitted by vegetation. It plays a key role in contributing to the formation of O_3 and affecting the lifetime of other species. Biogenic emissions are controlled by ambient environmental variables, most notably temperature and light. Increases in temperature normally lead to increased isoprene emissions. Future climate change (e.g., temperature increase) is expected to increase biogenic emissions, which will likely influence regional air quality.

Effects of Meteorological Variables on the Formation of O_3 and Aerosol

Episodes of high concentrations of surface O_3 usually occur during the summertime in stagnant air under dry, sunny weather conditions. On a local scale, intense solar radiation favors photochemical O_3 production. Ozone generally increases with increasing temperature and decreases with increasing relative humidity. Warmer temperature enhances O_3 production through affecting photochemical rate constants and biogenic emissions. Water vapor affects O_3 abundance through its consumption of $O(^1D)$ via the reaction $O(^1D) + H_2O \rightarrow 2OH$.

Meteorological variables affect the formation of precursors of aerosols through modulating the reaction efficiency. Once the semivolatile precursors of aerosols are formed, meteorological variables also affect the partitioning of those species between the gas phase and aerosols. The partitioning of semivolatile species depends highly on temperature and relative humidity. Low temperature and high relative humidity favor the partitioning of semivolatile species into the aerosol phase while high temperature and low relative humidity favor the partitioning of semivolatile species into the gas phase.

Effects of Meteorology on Dispersion of Pollutants

Meteorological processes (e.g., advection and vertical mixing) dictate the dispersion of pollutants. A good example of a favorable meteorological condition for heavy pollution is the horizontal advection induced by the coastal breeze in Los Angeles, California. The highly populated Los Angeles is surrounded by mountains on three sides and opens to the Pacific Ocean to the west and southwest. Pollutants accumulated over the urban areas in the stagnant morning air are regularly

transported downwind with the onset of the westerly sea breeze in the morning. The air mass is moved back after the onset of land breeze in the evening. The back and forth flow of the air is constrained by the surrounding mountains which allows the air to become highly enriched with pollutants, which likely leads to pollution episodes. Land/sea breezes are also reported to contribute to the elevated O_3 events in other regions such as Houston, Texas and Hampton, Virginia.

Vertical mixing events are reported to affect the variation of O_3 . Figure 3 shows observed O_3 , NO_x , wind vector, and temperature at Beltsville, Maryland, on 11 August 2010. During the period from 1:00 to 4:00 local time (LT), surface O_3 mixing ratio increased by about 30 parts per billion on a volume basis (ppbv) while NO_x mixing ratio decreased by ~ 25 ppbv (Figure 3). During the night of 10–11 August and most of 11 August 2010 the air mass came from the north. A cold front passed the research site, traveling from north to south on 11 August 2010. If O_3 increases resulted from the advection of an upstream polluted plume then mixing ratios of other pollutants such as CO, NO_x would be likely higher. However, NO_x level decreased as O_3 increased. The duration of this nocturnal O_3 increase (several hours) was similar to the 'leaky inversion' event, which was caused by the vertical exchange of air between the surface stable boundary layer and the residual layer above it. Since the residual layer had higher O_3 and lower concentrations of other pollutants, the vertical exchange of trace gases allowed decreases in surface NO_x and increases in surface O_3 .

Figure 3 Observed (top to bottom) O_3 , NO_x , wind vector, and temperature at Beltsville, Maryland, on 11 August 2010.

Vertical mixing could be also induced from wind shear and impair air quality near the surface. Nighttime low-level jets (LLJs) occur frequently in the Great Plains. The strong wind shear associated with LLJs was observed to affect the vertical redistribution of O_3 . On the night of 24–25 July 2003, nocturnal O_3 maxima were noticed in the presence of an LLJ (Figure 4). Such phenomenon occurred in Oklahoma quite frequently. Under a calm condition, surface O_3 normally decreased to very low levels (< 10 ppbv) between 20:00 and 22:00 LT due to dry deposition and NO titration. However, on the night of 24–25 July 2003, surface O_3 around Oklahoma city (OKC) increased after 20:00 LT and O_3 concentration stayed at elevated levels (> 40 ppbv) during most of the night. Such nocturnal O_3 maxima (or elevated O_3 concentration) were unlikely due to advection. On the nights of 24–25 July 2003 southerly wind persisted. If the nocturnal surface O_3 maxima were due to southerly advection of O_3 -rich air mass, the upwind site, Goldsby would have experienced higher O_3 maxima than the other downwind sites, which was clearly not the case (Figure 4). Instead, turbulence can be induced by the wind shear associated with the LLJs; the resulted vertical mixing can transport O_3 -rich air mass downward to the surface, thus explaining the frequently observed nocturnal O_3 maxima associated with the LLJs.

Vertical mixing could be also induced from cloud-top radiative cooling and affect the variation of pollutants in the boundary layer. During the springtime, anomalously low O_3 mixing ratios are frequently observed in the Arctic region. Such phenomena are called O_3 depletion events (ODEs). A few mechanisms are proposed to be responsible for the termination of the ODEs. One of the mechanisms is related to the vertical mixing induced from cloud-top radiative cooling. Downdrafts and compensating updrafts induced by the cloud-top radiative cooling can be sufficiently strong to reach the surface. The averaged vertical velocity in the presence of clouds may be as large as 0.6 m s^{-1} in the mixing layer. The vertical mixing associated with cloud updrafts and downdrafts

Figure 4 Time–height diagram of wind speed (WSP) in the atmospheric boundary layer and time series of surface O_3 observed on 24–25 July 2003 in the OKC metropolitan area. The left y-axis is O_3 mixing ratio while the right y-axis is the height for wind speed. The six EPA sites in the OKC metropolitan area where O_3 is observed are Moore, OKC, North OKC, Yukon, Choctaw, and Goldsby.

triggered by the clouds can mix the free tropospheric O₃-rich air downward to replenish the O₃ near the surface, thereby terminating the ODEs.

Air Pollution Modeling

Review of Three-Dimensional Air Quality Models

Air quality models (AQMs) integrate our knowledge on how physical and chemical processes affect pollutant concentrations and serve as a numerical laboratory. AQMs could be divided into two categories based on their reference frame: Lagrangian and grid-based Eulerian models. The Lagrangian models have simple structures and low requirements for computational resources, but have limitations in their formulation. The grid-based Eulerian models involve the least restrictive assumptions and are potentially the most powerful.

The grid-based Eulerian models can be further divided into two types based on the coupling between the meteorology (or dynamics) and chemistry in the model: offline vs online. In the off-line models, the meteorology representation/simulation is conducted prior to the simulation of chemistry. The off-line models use either prescribed observation-based or model-based meteorological fields at discrete times (normally hourly) to drive the chemistry models. The meteorological fields are interpolated to the appropriate transport time and coordinate frame for the use of the chemistry simulation in the off-line models. The off-line models are computationally efficient, and one set of meteorological data can be used to drive multiple chemistry simulations; however, they are incapable of simulating chemistry feedback to meteorology. In the real atmosphere, chemical and meteorological processes closely interact through climate–chemistry–aerosol–cloud–radiation feedbacks. Such feedbacks include: (1) aerosols may warm or cool the atmosphere by directly absorbing and scattering solar and terrestrial radiation; (2) aerosols may also indirectly affect cloud microphysics such as formation, albedo, lifetime, and precipitation through serving as cloud condensation nuclei. Those feedbacks are important; however, they cannot be simulated in the off-line models because of the decoupled treatments of meteorology and chemistry. The off-line models are traditionally used for air quality modeling due to the historical separation of meteorology and air quality communities, as well as our limited understanding of the climate–chemistry–aerosol–cloud–radiation feedbacks. In the online models, the meteorology and chemistry are simulated simultaneously in one coordinate frame. The online models make it possible to simulate the complex climate–chemistry–aerosol–cloud–radiation feedbacks given their closely coupled structure and treatments. In addition, the online models can utilize the detail meteorological process to drive chemistry simulation without interpolation.

Eulerian AQMs developed thus far can be categorized into three generations. The first-generation models are relatively simple models, in which dry deposition processes are not included. The second-generation models include deposition processes and have expanded chemical mechanisms in terms of both chemical species and reactions, and use improved numerical integration schemes. Both the first-generation and second-generation AQMs are off-line models. The off-line models

developed in the United States include the Sulfur Transport Eulerian Model, the Regional Oxidant Model (ROM), the Urban Airshed Model with Carbon Bond IV (UAM-IV), the Urban Airshed Model with Variable Grid (UAM-V), the Acid Deposition and Oxidant Model, the Regional Acid Deposition Model, the Community Multiscale Air Quality (CMAQ) Modeling System, SJVAQS/AUSPEX Regional Model Adaptation Project air quality model, the Multiscale Air Quality Simulation Program, and the Urban-to-Regional Multiscale model. ROM, UAM-IV, UAM-V, and CMAQ have been recommended by the U.S. EPA for regulatory applications. Several European regional AQMs are also off-line models, including the European Monitoring and Evaluation Programme model, the European Air Pollution Dispersion model, the Long-Term Ozone Simulation model, and the Regional Eulerian Model with three different chemistry schemes. It was envisioned that the third-generation models should be online models, in which the interactions among chemistry and meteorology will be treated.

Some simple online models were developed since 1960s; however, in most of those, the coupling between meteorology and chemistry was largely incomplete and only limited to a very few prognostic gaseous species. The first online fully coupled meteorology–air quality model is the Gas Aerosol, Transport, and Radiation AQM with a Mesoscale Meteorological and Tracer Dispersion model (referred to as GATOR/MMTD), which solves meteorological and chemical processes simultaneously and considers the two-way feedback between air quality and meteorological parameters. The first community online coupled meteorology–air quality model in the United States, Weather Research and Forecasting Model with Chemistry (WRF/Chem), is developed through the collaborative effort of several research institutes, agencies, and universities. In WRF/Chem, the air quality component is fully consistent with the meteorology component, both of which use the same transport scheme, same gridding, and same physics. The coupling between meteorology and chemistry components in WRF/Chem is relatively comprehensive. Various applications of online AQMs have shown their advantages over the off-line AQMs in many ways. For example, significant model errors of off-line AQMs for chemistry prediction may come from the low updating frequency of meteorological inputs, since some meteorological processes occur in a short timescale (<1 h). Such model errors are found rectified in online AQMs.

Since most of the PM_{2.5} is composed of secondary aerosol, simulating gas/particle mass transfer is essential for accurately predicting aerosol size/composition distributions. The treatment of gas/particle mass transfer in three-dimensional (3-D) AQMs, however, represents one of the major challenges for air quality simulations. Three approaches, equilibrium, kinetic (or dynamic), and hybrid, have been used to simulate gas/particle mass transfer in AQMs. The equilibrium approach assumes equilibrium between gas and aerosol. An aerosol thermodynamic model is used alone to determine the partitioning of semivolatile species between gas phase and aerosol phase. The kinetic approach does not rely on the equilibrium assumption. In this approach, the gas/particle mass transfer due to the difference between the ambient gas concentration and equilibrium gas concentration is explicitly simulated for each size section. The kinetic approach provides the most accurate solution when an appropriate numerical solver and a sufficiently fine

size resolution are used. However, its computational demands hinder its wide applications in 3-D AQMs. The hybrid approach provides a compromise between accuracy and efficiency by using the equilibrium approach for fine particles and the kinetic approach for coarse particles. The hybrid and kinetic gas/particle mass transfer approaches have been implemented in the Model of Aerosol Dynamics, Reaction, Ionization, and Dissolution (MADRID). The improved MADRID has been incorporated into WRF/Chem. The resulted modeling system, WRF/Chem-MADRID, will be used for the following case study.

Case Study of Air Pollution Modeling

Testbed, model configurations, and simulation design

WRF/Chem-MADRID is applied to a 5-day (28 August–2 September) episode from the 2000 Texas Air Quality Study (TexAQS-2000). During this episode more than twenty 1-h O_3 exceedances were observed in the Houston–Galveston–Brazoria area, among which six of them exceeded 150 ppbv. TexAQS-2000 was an intensive field study for air quality issues in the Houston–Galveston area. Houston is the fourth most populous city in the United States with a population of 4 million. Traffic and other anthropogenic activities result in high emission rates of NO_x and VOCs in this area. The biogenic emissions from the forested regions in the northeast of Houston also contribute to the total VOC emissions in the Houston area, depending on the wind direction. Another distinct characteristic of Houston as compared with other large cities in the United States is the numerous petrochemical industries in its surrounding area. Forty percent of the world's production capacity for low molecular weight alkenes is found in the Houston–Galveston area. The O_3 mixing ratios in Houston often exceed the former 1-h NAAQS of 120 ppbv (Note: As of 15 June 2005, EPA revoked the 1-h O_3 standard in all areas except the 8-h O_3 nonattainment Early Action Compact Areas). Under favorable meteorology conditions, the O_3 formation in Houston is rather rapid and some high O_3 events are observed even when the background O_3 mixing ratio is modest, making the O_3 problem in Houston quite unique. Annual mean $PM_{2.5}$ in southeastern Texas is close to the NAAQS of $15 \mu g m^{-3}$ and tends to be higher near urban and industrial areas of Houston. In this area direct emissions contribute approximately 40–50% of $PM_{2.5}$ while secondary sources account for 50–60% of $PM_{2.5}$ and inorganic species dominate the secondary PM. The southeastern Texas is affected by sea-salt emissions from the Gulf of Mexico as well as the anthropogenic emissions. Certain gas/particle mass transfer approaches may fail to predict the distribution of semi-volatile species for the areas where anthropogenic emissions are mixed with sea-salt emission.

The TexAQS-2000 was conducted to improve the understanding of the formation and transport of the pollutants along the Gulf Coast of the southeastern Texas. Intensive measurements of gaseous, particulate, and other hazardous air pollutants were made in the eastern Texas. Significant research efforts are devoted to investigate the pollution issues around the Houston–Galveston area. The modeling study in this work will focus on the effects of different gas/particle mass transfer approaches on the performance of 3-D air quality predictions over the eastern Texas.

The model inputs are set up for a region of $1056 \times 1056 km^2$ with a 12-km horizontal grid spacing and 56 layers vertically

from surface to 100 millibar (mb). Physics options used for the WRF/Chem-MADRID simulations include the Goddard short-wave radiation scheme, the rapid and accurate radiative transfer model for longwave radiation, the Yonsei University (YSU) boundary layer scheme, and the National Center for Environmental Prediction, Oregon State University, Air Force, and Hydrologic Research Lab's land surface scheme. Microphysics is turned off since there was no precipitation around Houston–Galveston area during this episode. The emissions of gas phase species were provided by the Texas Commission on Environmental Quality. The particulate matter emission was obtained from the EPA's 1999 National Emissions Inventory version 3. Eight size sections are used to represent the aerosol size distribution. To test the effects from the improvements of gas/particle mass transfer approaches, simulations are conducted with three mass transfer approaches, i.e., equilibrium, hybrid, and kinetic approaches.

Evaluation of meteorological predictions

Meteorological processes (e.g., sea breeze, low-level jets) play a vital role in O_3 events in Houston. Without properly capturing these meteorological processes, it is unlikely for the model to accurately predict the O_3 events in terms of time of occurrence, location, and peak values. The meteorological predictions are therefore first evaluated before the presentation of the chemical predictions.

Simulated temperature at 2 m (T_2) is evaluated at 32 observational sites. The observed mean temperature during the simulation period is as high as $31.2^\circ C$. Maximum surface temperature exceeded $40^\circ C$ on several days at certain sites during this episode. High temperatures accelerate chemical reactions and favor rapid production of secondary pollutants such as O_3 . WRF/Chem-MADRID captures the diurnal variation of temperature quite well for most sites (with a high correlation of 0.92 with the observation) and only overpredicts T_2 by $0.15^\circ C$.

On the average, wind speed is overpredicted by 8.7%. The mean observed wind direction is south-southwestly while the simulated mean wind is biased by 25° to be more westly. WRF/Chem-MADRID captures the diurnal variations of the wind fairly well at most sites. In addition to the overall statistics, the statistics for wind speed are calculated for nighttime and daytime separately. The performance of wind speed at night (with a correlation coefficient of 0.374, and a Normalized Mean Bias (NMB) of 39.8%) is worse than that during daytime (with a correlation coefficient of 0.492, and an NMB of -10.9%). The worse performance during nighttime may be due to the well-known model deficiency in accurately simulating nocturnal turbulent mixing near the surface, which is a common problem for all numerical weather prediction models.

Planetary boundary layer (PBL) height determines the vertical extent of dilution of pollutants and significant uncertainties are associated with the estimation of PBL height in current AQMs. Evaluation of PBL height at five radar wind profiler sites shows that overall the PBL height is overpredicted by 72.1%.

The high O_3 mixing ratios in the Houston–Galveston area are at times associated with the occurrence of sea breezes. Sea breeze circulations were clearly observed on 29–31 August 2000 over this area. WRF/Chem-MADRID reproduced the observed sea breeze development sequence fairly well even

Figure 6 Spatial distributions of maximum 1-h O_3 on 29, 30, 31 August, and 1 September 2000 predicted by WRF/Chem-MADRID with the equilibrium mass transfer approach. The observed values are indicated by shaded circles.

region. The sea breeze continues in the afternoon and the sea breeze front reaches more inland until 18:00 LT.

Results of chemical predictions

Figure 6 shows the spatial distributions of daily maximum 1-h O_3 . There is a cluster of sites experiencing high O_3 mixing ratios around Houston on all 4 days. Substantial photochemical production of O_3 following the emission of precursors (e.g., VOCs and NO_x) from the Houston area leads to prominent O_3 -rich plumes on 30 and 31 August. Driven by the large-scale westerly wind, the O_3 -rich plumes are eastward moving. South part of Louisiana is affected by the O_3 -rich plumes. Such a regional transport pattern was reported to impair the air quality in Louisiana at times.

WRF/Chem-MADRID captures the diurnal variations of surface O_3 at 60 observational sites quite well (Figure not shown). The hourly O_3 throughout the simulation period is underpredicted by 4.6% (1.8 ppbv) from WRF/Chem-MADRID with the equilibrium mass transfer approach (Note: Different mass transfer approaches had negligible effects on O_3

predictions). The daytime hourly O_3 is only underpredicted by 0.4% (0.2 ppbv). This indicates that WRF/Chem-MADRID captures the O_3 formation mechanisms reasonably well.

The differences of daily average $PM_{2.5}$ predicted by WRF/Chem-MADRID with the three different mass transfer approaches are trivial over the inland area while the differences are more prominent over the sea and some coastal areas (Figure 7). The $PM_{2.5}$ concentrations in the plume originating from Houston predicted by the equilibrium approach are much higher than those predicted by the hybrid and kinetic approaches, and the differences are mainly due to nitrate (NO_3^-). The equilibrium approach predicts more fine nitrate (NO_3^- in particles with diameter less than $2.5 \mu m$) and less coarse nitrate (NO_3^- in particles with diameter larger than $2.5 \mu m$) than the hybrid and kinetic approaches (Figure 8). The spatial distribution of simulated nitrate plume matches that of the sodium (Na^+) plume quite well (Figure not shown). Sodium is a tracer of sea-salt aerosol and it is emitted together with chloride (Cl^-) from the ocean. Most sodium chloride is emitted in the coarse mode. Sodium stays in the aerosol phase

Figure 7 Spatial distributions of daily average $\text{PM}_{2.5}$ mass concentrations simulated with (left to right) the equilibrium, hybrid, and kinetic mass transfer approaches on (top to bottom) 30, 31 August, and 1 September 2000. The measured values are indicated by shaded circles.

since it is nonvolatile, while chloride may exchange between aerosol and gas phase. Nitrate enters aerosol phase through the chloride depletion process ([R4]):

Since the hybrid and kinetic mass transfer approaches both solve the mass transfer for coarse particles kinetically, the chloride depletion process is correctly simulated when anthropogenic pollutant plumes (which contain plenty of

nitric acid, HNO_3) mix with sea salt (which contains sodium chloride). However in the equilibrium approach, the aerosol phase is treated together to equilibrate with gas phase. Even though [R4] can still be simulated by the equilibrium approach, the transferred mass into aerosol phase is redistributed among each section based on initial sulfate (SO_4^{2-}) distribution. Since most sulfates are in the fine mode, the transferred nitrate from the chloride depletion process is erroneously redistributed mostly to the fine mode by the

Figure 8 Aerosol size/composition distributions at a coastal site, i.e., Galveston (GALC) on 30 August 2000 predicted by WRF/Chem-MADRID with (left to right) the equilibrium, hybrid, and kinetic gas/particle mass transfer approaches. The x -axis is the diameter of aerosol.

equilibrium approach. Thus WRF/Chem-MADRID with the equilibrium approach predicted higher $PM_{2.5}$ in the coastal area. Due to the prevailing large-scale westerly wind, the $PM_{2.5}$ concentrations in southern Louisiana are enhanced by the pollution plumes originated from Houston (Figure 7).

Improvement of Simulation of Air Pollution Meteorology

Uncertainties of current AQMs

The accuracy of air quality simulations is affected by the uncertainties associated with the model treatments for various processes, including vertical mixing, dry deposition, and chemical mechanisms. Vertical mixing is handled by the PBL scheme in the models. The uncertainties associated with the PBL schemes remain one of the main sources of inaccuracies in air quality simulations. Three PBL schemes in the WRF model, i.e., the YSU scheme, the asymmetric convective model, version 2, (ACM2) scheme, and the Mellor–Yamada–Janjic (MYJ) scheme were evaluated in a modeling study covering the domain of the South Central United States. In that study, the WRF simulations underpredict temperature and overpredict moisture near the surface. Use of the local-closure MYJ scheme produces the largest bias. The YSU and ACM2 schemes both lead to predictions of higher temperature and lower moisture, and thus smaller biases, than the MYJ scheme in the lower atmosphere during daytime because of their stronger vertical mixing. Stronger vertical mixing causes stronger entrainment at the top of PBL, which helps warm and dry the PBL. In the local-closure MYJ scheme, the only entrainment that develops must come from local mixing. Entrainment from penetrating plumes or large eddies is not accounted for. Underestimated entrainment is shown to at least partially cause the colder PBL predicted by the WRF model with the MYJ scheme. During nighttime the WRF model with the YSU PBL scheme produces higher temperatures and lower moisture than with the other two schemes in the lower atmosphere because of its enhanced mixing during nighttime.

Parameter estimation

The accuracy of model simulations is dictated by the uncertainties associated with model treatments for various processes.

Parameter estimation offers a way to improve the accuracy of those model treatments. Parameter estimation is a technique for determining the best value of certain model parameters through data assimilation or similar techniques. When applied to parameterizations of meteorological processes, one hopes to identify optimal parameter values within a given parameterization, with ‘optimal’ defined over some appropriate domain in space and time.

Advanced data assimilation methods, e.g., variational approaches and the ensemble Kalman filter (EnKF), are capable of extracting from observations significant information about the model parameters in addition to the model state. They have been used to counter model errors due to incorrect parameters by calibrating those parameters simultaneously with the model state during the analysis process. The EnKF was applied to estimate the flow-dependent optimal values of two parameters fundamental to the performance of a PBL scheme in the WRF model. Parameter estimation EnKF results in a significant reduction in the model biases of both wind and temperature. Also, deterministic forecasts with updated parameters outperform forecasts with standard parameter settings.

Ensemble simulation

There are dramatic uncertainties in the air quality simulations due to uncertainties in the initial meteorological/chemical conditions and model treatments of physical and chemical processes. Even with plentiful observations, analysis inaccuracies are unavoidable, so a single-minded pursuit of improved initial conditions is inadvisable. Given the uncertainties associated with various model treatments under various conditions, improving model performance in a single deterministic simulation through pursuing perfect model treatments for all the conditions is also unlikely. Instead, ensemble simulations should be utilized to span the range of possible outcomes on a given day, and that uncertainty should be incorporated into the regulatory analysis. As with simulations, deterministic photochemical forecasts are similarly unlikely to be successful. An ensemble forecasting system, incorporating as many sources of error as possible, can provide guidance on not only the most likely evolution of pollutants but also the range of possibilities.

Introduction

From the earliest times writers and artists have given us their verbal and pictorial images of the characteristic and repeating patterns of the irregular eddying motions in the lower part of the atmosphere. One can see their form in long streaks of snow (called by one writer 'rivers of wind'), vortices spurring from the desert surfaces in sandstorms, billowing fog-banks and towering cumulus clouds reaching 10 km upwards to the tropopause (e.g. Scorer 1978). The scientific study of these coherent structures began in 1802–03 when Lamarck in Paris and Luke Howard in London noted that there are only a few types of clouds which can therefore be usefully classified. Howard, whose nomenclature (cumulus, stratus, cirrus) has only been slightly changed by later research, had the insight to realize that those structures define the essential dynamics governing the flow. The importance of his insight was recognized by Osborne Reynolds in 1895 when he was establishing the fundamental statistical laws of the 'new' subject of turbulence.

It is now generally accepted that the comprehensive study of any type of turbulent flow, especially atmospheric flows, requires combining the statistical approach with the description and analysis of coherent eddy structures, i.e. motions driven by the unstable inertial and buoyancy forces in the flow that have a characteristic, repeatable and persistent form yet are internally unpredictable and occur randomly in space and time. Development of the dual approach has improved the understanding of the approximations in the statistical approach (as Prandtl indeed first pointed out in 1925), while the statistical analysis also provides a quantitative model for the coherent structures (e.g. Holmes et al. 1996).

When the only systematic measurements were obtained from time series recorded by isolated instruments, it was natural that the study of atmospheric motions was essentially statistical, analyzing correlations and spectra (Panofsky and Dutton 1984) and then using the governing equations of fluid flow to calculate the mean dynamics and energetics, following Reynold's analysis. However, the new technology and capability of multipoint tower and radar measurements (e.g. Kaimal and Finnigan 1994) together with the computational capacity to perform numerical simulations (at varying degrees of accuracy) have now provided nearly complete descriptions of the instantaneous and time development of coherent structures in different atmospheric conditions. These broadly confirm earlier concepts based on observations, clouds, bird flight and dust patterns.

Structures tend to be particularly well defined where one type of structure dominates the boundary layer, such as thermal plumes in unstable boundary layers or Kelvin–Helmholtz billows (which e.g. occur in the stable layer), the undulating top of the mixed layer and sea breeze fronts. When there are

more types of structures or where these are evolving from one form to another, there are no dominant structures and their descriptions are less precise. Quantitative evaluation of their velocity and pressure fields have shown that structures contribute significantly to the overall dynamics of the flow. That is why they tend to determine the form of the velocity spectra, e.g. of the vertical and horizontal components, especially in the distorted eddy structure near the ground. Just as important in practice, structures also affect the statistics of extreme events, such as very large gusts or high downbursts of pollution.

This survey article reviews the various coherent structures in atmospheric turbulence. First the horizontally homogeneous boundary layer is considered, then the structure of the boundary layer over inhomogeneous and rough terrain and equally importantly over the oceans.

The Stationary, Horizontally Homogeneous Atmospheric Boundary Layer Over Flat Terrain

In **Figure 1** are classified the horizontally homogeneous atmospheric boundary layer in terms of the ratio h/L_{MO} between the boundary-layer height h and the Monin–Obukhov length L_{MO} and the ratio z/h , where z is the height above the surface. The Monin–Obukhov length characterizes the height above the ground where buoyancy starts to dominate shear. Since the forms of eddy structures depend on the balance of forces within them and on the proximity to boundaries, the type of coherent structure is characterized by the two parameters h/L_{MO} and z/h . Near the surface, when $h/|L_{MO}| \leq 1$, the main statistical features of the boundary layer tend to be determined locally in terms of z and local fluxes of momentum and buoyancy. However, in the upper part of the boundary layer the large-scale eddying motion are also affected by interactions between the troposphere and the free atmosphere above the boundary layer if these are significant. This means that the typical frequency of the large eddies in the boundary layer, e.g. u_*/h , where u_* is the friction velocity, becomes comparable with the buoyancy frequency of the stable troposphere N_T or the Coriolis parameter f .

The Unstable or Convective Boundary Layer ($h/L_{MO} < 0$)

An unstable or convective atmospheric boundary layer usually occurs when the boundary layer is heated at the surface, which is being warmed by solar radiation. Convective layers can also form when the top of the boundary layer consists of a closed cloud deck, e.g. stratocumulus clouds. In that case the top of the boundary layer cools owing to long-wave radiation from the clouds. The cool air descends which sets up convective motions in the boundary layer. Here, however, the discussion is

Figure 1 Diagram of the various coherent structures in the atmospheric boundary layer in term of the dimensionless height z/h and the dimensionless stability parameter h/L_{MO} . restricted to the convective boundary layer developing above a surface.

The principle of convection applies to a layer of fluid with a thickness h subjected to a vertical temperature difference ΔT with the high temperature at the bottom and the cold temperature at the top. The layer may become unstable when the buoyancy forces exceed the damping force of viscosity and the tendency of heat to diffuse away from convecting elements. This criterion is usually expressed in terms of the Rayleigh number, defined as

$$Ra = \frac{\beta \Delta T h^3}{\kappa \nu} \quad [1]$$

where β is the buoyancy parameter, κ the heat conduction, and ν the kinematic viscosity. In air, $\beta = g/T_0$, with g the acceleration of gravity and T_0 the absolute mean temperature of the fluid layer.

The critical value of Ra when fluid motions first appear lies in the neighborhood of $Ra \approx 2000$. The first instability mode just beyond this critical value is a flow pattern of two-dimensional rolls. When the Rayleigh number becomes larger, other modes come into play and the flow assumes a pattern of hexagonal cells with a width about equal to the layer of the fluid. These are also known as Rayleigh–Bénard cells.

In the atmosphere the Rayleigh number is typically $Ra \approx 10^{18}$, which is so high that the convective flow is highly turbulent with several types of flow structures. Hexagonal cloud patterns can sometimes be observed, e.g. when air is transported from a cold sea surface over a land surface at higher temperature which sets up strong convection. However, the horizontal scale of these cloud patterns is always much larger than the boundary layer depth, say from 50 to 100 km, which makes them quite different from the Rayleigh–Bénard cells. Generally, the structure of convective eddies, as well as the profiles of the statistical properties of the turbulence, are determined by the ratio of the surface buoyancy flux $F_B = \beta w' \theta'$ to the rate of transfer of mechanical energy (u_*^3/h) caused by turbulent shear stress. Alternatively, this ratio may be expressed as h/L_{MO} , where $L_{MO} = -u_*^3/F_B$. Note that this ratio

also indicates the relative strength of the convective turbulent eddies, with a typical velocity w_* , and the shear-dominated eddies, with a typical velocity u_* , since $h/|L_{MO}| = (w_*/u_*)^3$.

Let us now concentrate on the flow patterns found in the convective atmospheric boundary layer, which in **Figure 1** is the region with $-h/L_{MO} > 10$. In the middle and upper part of the boundary layer, i.e. $z/h > 0.1$, the flow organizes itself in large-scale plume- or puff-like structures in which there is a strong flow upwards carrying the warm air from the surface to the top of the boundary layer. Plumes tend to form when there is a constant heat flux at the surface, for example by strong thermal radiation. The upward motion is compensated by a weak downward motion in the area outside the plumes. The consequence of this velocity structure is that the area-averaged vertical velocity fluctuations have a positive skewness.

Near the top of the boundary layer, i.e. $z/h > 0.8$, where there is usually a temperature inversion, the plume structures impinge on this stable layer. As a result the strong vertical motions are converted into horizontal velocity fluctuations which generate Kelvin–Helmholtz type instabilities in the velocity profile near the boundary layer top. Owing to these instabilities, air from above the inversion is mixed with air of the convective layer. This is called entrainment, and it causes the boundary layer to grow during the day. As a result of impinging convective eddies, wave motions are set up which are partly trapped in the inversion layer and partly propagate into the free atmosphere.

Near the surface, in the so-called surface layer, i.e. $z/h < 0.1$ heating produces structures with a size that increases with distance z above the ground. Owing to their mutual entrainment or coalescence, these small plumes organize themselves into larger structures. When $-h/L_{MO} > 10$ these take the approximate form of hexagonal spoke patterns. The lateral extent of large-scale structures in the surface layer is determined mainly by the blocking of the relatively wide downdrafts as they impact on the ground. This mechanism produces a horizontal wind shear close to the surface and generates sheared eddies with a typical velocity u_* , as also occurs in unstratified and stable boundary layers.

When $1 < -h/L_{MO} < 10$ the convective boundary layer occurs in the combination with a mean wind. In that case the

resulting shear is able to organize the plumes into rolls with a horizontal separation of the order of magnitude close to the boundary layer height. These can sometimes be observed as cloud streets.

Stable Boundary Layer

A stable boundary layer occurs when the vertical (potential) temperature gradient in the boundary layer is positive. This is usually associated with the heat flux and the associated buoyancy flux F_B being negative at the surface, i.e. $h/L_{MO} > 0$. However, stable boundary layers may also occur in spatially developing flows, such as in cold fronts when the boundary layer is significantly cooler than the air above. In all cases the Richardson number $Ri > 0$ with Ri defined as

$$Ri = \beta \frac{\partial \bar{\Theta} / \partial z}{(\partial \bar{U} / \partial z)^2}$$

where $\bar{\Theta}$ is the mean potential temperature and $\bar{U}$ the mean velocity. The coherent structures are not as energetic as in convective and neutral flows (see the following subsection on the shear-driven or neutral boundary layer) because buoyancy forces suppress the vertical displacements of fluid elements. By decorrelating vertical and horizontal motions when Ri is greater than its critical value of about $\frac{1}{4}$, the buoyancy forces effectively suppress the input of energy from the mean flow to turbulence. But in such situations wave motions in the upper part of the boundary layer can induce turbulence with significant energy. Turbulence can survive only if sufficient turbulent energy is produced locally by the breakdown of such waves or by the mean shear. The influence of the stable stratification forces reduces the vertical dimensions of the eddy structures in relation to their horizontal dimensions to such an extent that, as clouds and chimney plumes reveal, the eddies take the shape of pancakes or 'blinis'. This is why the turbulent structures in the middle of the stable boundary layer, i.e. $z/h > 0.1$, are not closely coupled to motions at the surface. As with the convective boundary layer, small sheared eddy structures, e.g. longitudinal vortices with diameters of a few centimeters, are observed near the surface.

Experiments show that the turbulent pancake structures persist even when the stable density gradient is so great that Ri exceeds unity. In this situation the turbulence decays, but periodically it tends to be reenergized by overturning internal waves of local shear-driven instabilities as layers move over each other. In the quiescent periods between these events the turbulence tends to collapse into layered chaotic motions in horizontal planes that have some resemblance to two-dimensional turbulence, as observed in the ocean and the laboratory, and as produced by numerical simulations.

The Shear-Driven or Neutral Boundary Layer

As the heat flux to and from the surface decreases and the wind speed increases, i.e. $h/|L_{MO}| \ll 1$, progressively a greater proportion of the eddy motion in the boundary layer becomes determined by wind shear, and buoyancy forces become negligible. Then the boundary layer is neutrally stable and is similar to those found in engineering flows where the governing similarity parameter in the Reynolds number $Re = u\ell/\nu$,

where u and ℓ are the characteristic velocity and length scale of the flow. However, there are also differences because the Reynolds number in an atmospheric boundary layer ($Re \approx 10^6$) is in general much larger than the Reynolds number in an engineering flow ($Re \leq 10^5$). In the atmosphere, as observation of 'cat's-paws' moving over the sea surface show very clearly, the large-scale eddies interact with the surface by impinging downward and by 'scraping' along the surface. This top-down production of turbulence differs from the bottom-up instability or 'bursting' processes which occur for low- and moderate-Reynolds-number turbulence. The consequence is that the eddy motion at different heights of the boundary layer are well correlated and the variance of horizontal velocity fluctuations decreases only slowly with height in the atmospheric surface layer, in contrast with the quite rapid variation as a function of height in engineering boundary layers. Another effect is that the length scale of the horizontal velocity fluctuation is much larger in the high-Reynolds number atmospheric case.

Above the surface layer, i.e. $z/h > 0.1$, if the troposphere above the boundary layer is very weakly stratified then the wind velocity profile and eddy structure is influenced by Coriolis acceleration f due to the earth's rotation, and this results in a change of direction of the velocity with distance from the surface. This means that the structure is (weakly) dependent on the ratio $u_*/(fz_0)$ and the boundary layer depth is proportional to u_*/f . Owing to this change in wind direction the velocity profile in the 'Ekman' layer (named after its discoverer) becomes three-dimensional and contains an inflection point where the velocity gradient is maximum. Because of both the instability of this profile and the anisotropy of Reynolds stresses, eddy structures develop in the form of rolls, approximately directed along the wind direction. These longitudinal rolls enhance the vertical transport of momentum to such an extent that, except in ideal neutral conditions, the change in mean wind direction with height is usually less than predicted by Ekman's theory and quite often in the opposite direction.

Eddy Structure in Boundary Layers Over Very Rough and Inhomogeneous Terrain

Over snowfields, deserts and prairies, the land surface is effectively made up from small, regular 'roughness elements' such as snow and sand particles or grass and bushes. But over more irregular terrain and inhabited areas there are larger obstacles such as mountains, buildings and trees that affect the mean flow and the eddy structure significantly. Both types of surface roughness slow down the flow and affect the mass and heat transfer to the surface. Note that even if these obstacles are smoothly shaped, such as hills and valleys with low slopes (say less than $\frac{1}{3}$) or water waves in case of air flow over the sea, they have a substantial effect on the mean structure of the atmospheric boundary layer, especially in stably stratified conditions. But when the obstacle slopes are large (such as mountains with slopes more than $\frac{1}{3}$) or when they are shaped with sharp angles (such as buildings) they are described as bluff and they generate a quite distinct eddy structure.

For the former case, of smoothly shaped obstacles in neutral stratification, it is found that in the 'innerlayer' (which over a hill or wave is typically less than about $\frac{1}{20}$ of the length of the

hill) the turbulence and eddy structures are similar to those over a flat surface. However in the outer region the eddy structures are significantly distorted, leading for example to a amplification of vertical turbulence at the top of the hill and a slight reduction of the horizontal fluctuations. When several hills lie perpendicular to the wind, the distortion of the mean shear by the undulating motion leads to large-scale rolls of streamwise vortices.

There are special characteristics of eddies generated by the flow over bluff obstacles, depending on whether their height δ is much smaller than the boundary layer depth h , such as in the case of buildings, or when δ is comparable with h , as in the case of mountains. Roller eddies (or Kelvin–Helmholtz billows) are produced in the intense shear layer separating the fast-moving stream of air over the top of the obstacles from the slow-moving wakes on the downwind side. These roller eddies tend to transform downwind into longitudinal eddy structures over a distance of a few obstacle heights. There tends to be a distinct boundary between the eddies produced by the obstacle shear layers and those of the oncoming boundary layer which is visible when smoke is released into the wake regions. Notable features of isolated bluff bodies are the horseshoe vortices which are wrapped around the obstacle and then extend downwind. These are visible by an indented region on a sandy or snow-covered surface. They interact unsteadily with the vortical eddy structures shed from the obstacle.

By contrast convective turbulence over hills and other rough terrain is broadly similar to that over level terrain, although the eddy structures have some weak correlation with the surface elevation, surface albedo, and temperature. When the slopes become quite large, the plumes tend to develop preferentially on the slopes and may converge into a single large plume at the top of the mountain. These phenomena are well known to glider pilots, who make use of ascending air currents to stay aloft.

In the stably stratified flow over sloping terrain and smoothly shaped obstacles, such as valley flow at night, the mean flow pattern is determined by a complex interaction between the geostrophic flow and the buoyancy-driven flow down the slope. Since the flow direction tends to vary with height, the eddy structures are of small scale and highly sheared. They are also quite intermittent, because the rate of cooling and the slope-driven flow varies from place to place. Such slope flows tend to have a billowing eddy structure characteristic of gravity currents with a strong local vertical mixing at the head of the current and weaker mixing downwind.

Coherent Structures at the Small Scales

Many measurements of spectra and correlations confirm hypotheses of G. I. Taylor and A. N. Kolmogorov that at the smallest scales of motion the basic statistical structure of turbulence is isotropic. However, even qualitative observations, for example of particle motion and smoke patterns, show that when examined closely, even at the smallest scales, turbulence contains structures with a distinct geometrical form that is elongated and far from isotropic. These two findings are

nevertheless consistent, because these anisotropic structures have no particular orientation, so that their statistical distribution is isotropic. These regions consist of long, elongated threads of high vorticity (parallel to the threads). They are sometimes called ‘worms’. These relatively long-lived structures are the residual motions resulting from the rolling up of short-lived vortex sheets. The dynamics of small-scale isotropic turbulence is determined by the vorticity production and dissipation in these vortex sheets, which are formed by strong straining or deforming motions. The duration of this process is typically short, say of the order of the Kolmogorov time scale (seconds in the atmosphere), and is therefore intermittent.

Despite their small size these structures play a crucial role in environmental processes. The straining affects mixing and chemical reactions, while the vortices affect processes that involve small particles, such as aerosols or cloud droplets. The swirling motion in these vortices or worms cause particles heavier than air to be spun out of them. In other words the worms act like centrifuges, and this results in flow regions with few particles and regions with many particles, also called preferential concentrations.

The effect of preferential concentration may have two consequences in the process of warm-cloud rain formation. The first is related to the fact that in regions where there is a small concentration of water droplets almost no condensation of water vapor on droplets can take place. As a result the water vapor density may grow and become supersaturated again, which implies that new cloud droplets can be formed, resulting in a broad distribution of cloud droplets.

The second effect is related to the process of collision and coalescence of cloud droplets. For cloud droplets in the range of 20–50 μm , the strong vortices may influence the trajectory of the droplets such that they preferentially fall along the side of the vortex with the downward-moving velocity. As a result the settling speed is increased and may reach a factor 80% more than the settling speed of a cloud droplet in quiescent air. Together with the increase in concentration this may result in a larger collision probability and thus in droplet growth due to coalescence. When the droplet becomes larger that about 50 μm the vortices can no longer deflect the droplet from its vertical fall trajectory. In that case the vortices will decrease the fall velocity somewhat with respect to the fall velocity in quiescent air.

Significance of Coherent Structures for Practical Problems

Coherent structures in the atmosphere need to be understood and described in order to deal more effectively with engineering and environmental problems. Examples are wind energy, wind loading on structures, aircraft operation, blowing of dust and snow, propagation of electromagnetic waves, wind shelter design, and dispersion of air pollution. Study of coherent structures is also helpful in interpreting statistical data (such as spectra, correlations, and probability distributions) and can also be used for interpolation when data are not available or for extrapolation to more complex situations. A few examples are now given.

In the convective boundary layer, the structure of the thin updrafts and the broad downdrafts causes the position of the maximum surface concentration of an elevated source of pollution to be much closer to the source than in the neutral boundary layer. This effect was not included in early atmospheric dispersion models, in which the turbulence was assumed to have a Gaussian distribution and which therefore made substantially incorrect predictions. The interaction between the large, buoyancy-dominated eddy structure in the upper part of the layer and the shear structure near the surface also has to be understood when estimating the variation of the dispersion from low-level sources.

The eddy structure in the stable boundary layer is also of importance in the dispersion of air pollutants, especially at night and in cold winter conditions. The way the turbulence is unsteady and very sensitive to a slope (even as low as 10^{-2}) helps explain anomalous effects and the limitations of simple predictive models. For agriculture in valleys where frost pockets form, these intermittent mixing events need to be predicted and if possible avoided by artificial mixing (e.g. by fans or burners).

When there are very strong winds, the boundary layer is neutrally stratified. The calculation of wind energy and wind loads on structures needs information about the turbulent spectra. Spectra show that eddies near the ground are larger in the flow direction than those higher in the boundary layer. This surprising result, widely used in engineering calculations, can be understood in terms of elongated eddies very close to the ground. But near buildings, these eddies are broken up and the spectra change. The rapid change with height of the eddy motion over hills has an effect on the performance of wind turbines, and this should be taken into account in an assessment of the viability of wind energy projects.

Introduction

The boundary layer is the layer of the atmosphere that is influenced directly by the roughness and energy balance of the surface. Much of the character of the boundary layer, therefore, is impressed upon it by the particular nature of the underlying surface. Hence we consider the kinds of boundary layers that develop over surfaces that are inhomogeneous either because the surface cover is changing or because the surface is not flat. Although, more often than not, natural surfaces exhibit both topography and changing surface cover, it is more instructive to deal with these two elements of complexity separately.

Changing Surface Cover

Here we are concerned with horizontal inhomogeneity, ranging from simple changes between one surface type and another to continual changes such as might be seen in farms with fields planted with different crops. Atmospheric flow over such terrain is characterized by the appearance of internal boundary layers over each new surface. If the new surface continues sufficiently far downstream without further change, the new internal boundary layer replaces the old boundary layer and eventually a new geostrophic balance is struck between the surface and the synoptic flow above the boundary layer. If the surface character changes continually, however, the impact of each internal layer only extends up to some blending height, above which the total boundary layer behaves as if it were flowing over a surface with properties that are some average of the different patches.

Topography

Hills and valleys affect boundary layer flow because the pressure field that develops as the atmosphere flows over them accelerates and decelerates the near-surface flow. In a relatively thin layer near the surface, analogous to an internal boundary layer, changes in turbulent stresses strongly affect the mean flow, but at higher levels the changes in mean wind speed are essentially inviscid. The pressure field that develops about any given hill is strongly dependent upon the stratification of the atmosphere flowing over it, which can be characterized by a Froude number. Hence, the scale of the topography profoundly affects the resultant boundary layer flow patterns. Those over a very large hill, whose pressure field is largely determined by the displacement of the stratified synoptic flow above the boundary layer, are quite different from those over a smaller hill, where flow displacement is confined within the neutral or unstable boundary layer. Here we will confine our attention to smaller hills.

We will be concerned with the boundary layers that develop over terrain with these two kinds of complexity, due to surface cover and to topography, and will concentrate especially on

two aspects of their description: the windfields that we observe within them and the surface stresses beneath them. Our introduction of spatially averaged equations below suggests one motivation for this. Mathematical model used for climate or weather prediction have horizontal resolutions $50 \times 50 \text{ km}^2$ so that the windspeed averaged over grid cells $500 \times 500 \text{ km}^2$ in area has to be related to some average of the surface properties within the cell. At the same time we want to know how to relate measurements of windspeed and other variables at points in an evolving boundary layer to the surrounding landscape.

Notation

We use a right-handed rectangular Cartesian coordinate system, $x_i(x, y, z)$ with $x_1(x)$ aligned with the mean velocity at the surface and $x_3(z)$ normal to the ground surface. Velocity components are denoted by $u_i(u, v, w)$ with $u_1(u)$ the streamwise component and $x_3(w)$ the vertical component. Time averages are denoted by an overbar (e.g., $\bar{u}$) and departures from the time mean by a prime (e.g., u'). Area averages over the x - y plane are represented by angle brackets (e.g., $\langle \bar{u} \rangle$).

Changing Surface Cover

We will look first at simple changes of surface roughness such as those between bare soil and an irrigated crop. Once we have established the nature of simple transitions from one type of surface to another we will be in a position to describe the boundary layer over patchy surfaces.

Local Advection: The Wind Field

Local advection refers to situations where the effects of surface changes do not propagate above δ_{ASL} , the depth of the atmospheric surface layer. Imagine an equilibrium surface layer flow, characterized by a logarithmic profile with roughness length z_{01} and displacement height d_1 , eqn [1].

$$\bar{u}_1(z) = \frac{u_{*1}}{\kappa} \ln\left(\frac{z - d_1}{z_{01}}\right) \quad [1]$$

$u_{*1} = \sqrt{\tau_{01}}$ is the friction velocity, defined as the square root of the kinematic surface stress τ_0 , and κ is von Karman's constant. This flow encounters a new surface with roughness length z_{02} and displacement height d_2 . We will assume that the boundary is perpendicular to the surface wind vector. As the air flows over the new surface it either slows down because of increased surface friction (smooth-rough change, $z_{02} > z_{01}$) or speeds up because the surface friction falls (rough-smooth: $z_{02} < z_{01}$). The effect of this acceleration or deceleration, which is initially confined to the air layers in contact with the new

surface, is diffused vertically by turbulence, and the effect of the change is felt through a steadily growing internal boundary layer of depth $\delta_i(x)$ (see Figure 1(a)).

The effects of the change are also transmitted by pressure forces that are associated with any change in streamline height that follows if d_1 is not equal to d_2 and this pressure perturbation is not confined to the internal boundary layer. Its effect is negligible, however, except very close to the transition, even when the change in displacement height is significant and for the rest of this section we will ignore it. From now on we will also avoid writing $z - d$, assuming that the origin of the z coordinate is adjusted appropriately to include d .

The strength of the roughness change can be characterized by the ratio of the roughness lengths, M^* , or its logarithm, M (eqn [2]).

$$M^* = \frac{z_{01}}{z_{02}} \quad M = \ln\left(\frac{z_{01}}{z_{02}}\right) = \ln(z_{01}) - \ln(z_{02}) \quad [2]$$

Within the internal boundary layer the flow displays characteristics of the downstream surface. Outside it, apart from the small perturbation caused by the pressure pulse at the transition, the flow field is identical to that upwind (see Figure 1(b)). The internal boundary layer depth $\delta_i(x)$ is usually defined, therefore, as the height at which the downwind velocity $\bar{u}_2(z)$ attains a fixed fraction (e.g., 99%) of its upwind value at the same height.

The growth of the internal boundary layer is caused by turbulent diffusion and, if we take the characteristic diffusion velocity as $u_{*2} = \sqrt{\tau_{02}}$, the downstream friction velocity, then we can write eqn [3].

$$\frac{d\delta_i}{dx} = \frac{Bu_{*2}}{\bar{u}_2(z)} \quad [3]$$

Figure 1 (a) Schematic diagram of internal boundary layer growth. The inner equilibrium region is marked by the dashed curve. This region is not expected to begin until some distance after the roughness change. (b) Logarithmic velocity profiles after a roughness change. The upwind profile is denoted by a dashed line.

To integrate eqn [3] we need an expression for $\bar{u}_2(z)$; for $\delta_i < \delta_{ASL}$ the simplest assumption is that shown in eqn [4].

$$\bar{u}_2(z) = \frac{u_{*2}}{\kappa} \ln\left(\frac{z}{z_{02}}\right) \quad [4]$$

Then stipulating that $\delta_i(x) = 0$ at $x = 0$, and locating the origin of coordinates at the roughness change, from eqns [3] and [4] we obtain eqn [5].

$$\frac{\delta_i(x)}{x} \left[\ln\left(\frac{\delta_i(x)}{z_{02}}\right) - 1 \right] = B\kappa \quad [5]$$

Equation [5] provides a qualitative description of the growth of the internal boundary layer and, with the experimentally determined constant $B \approx 1.25$, provides a good quantitative measure of $\delta_i(x)$ for smooth-rough changes and also for rough-smooth transitions if M is less than 2. When the rough-smooth change is larger ($M \geq 2$), eqn [5] tends to underestimate the growth in $\delta_i(x)$ because then diffusion downstream of the roughness change is controlled for some distance by the slowly decaying upstream turbulence.

To obtain eqn [5] we assumed that the velocity profile within the internal boundary layer was logarithmic all the way up to $\delta_i(x)$. This is a gross oversimplification, however. In Figure 1(a) we have identified an inner equilibrium layer, $\delta_e(x)$ at the bottom of the internal boundary layer. Only in this layer has the flow attained local equilibrium with the new surface with the shearing stress $\tau_2(z)$ approximately constant with height and the velocity profile $\bar{u}_2(z)$ obeying eqn [4]. An estimate for $\delta_e(x)$ can be obtained by first writing an approximate equation for the streamwise momentum balance that ignores any pressure perturbation at the roughness change and also assumes that the changes in the flow field are small

$$\bar{u}_1(z) \frac{\partial \Delta u}{\partial x} \sim \frac{\partial \Delta \tau}{\partial z}$$

where $\Delta u = \bar{u}_2(z) - \bar{u}_1(z)$ and $\Delta \tau = \tau_2(z) - \tau_1(z)$. If we now insist that for local equilibrium to obtain below $\delta_e(x)$, the integral from $z = 0$ to δ_e of the advection term on the left-hand side of this equation must be negligible compared to the perturbation in surface stress, $\tau_{02} - \tau_{01} = u_{*2}^2 - u_{*1}^2$, we obtain

$$\frac{\delta_e(x)}{x} \sim 2 \left(\frac{u_{*2}}{\bar{u}_2} \right)^2$$

Whence

$$\frac{\delta_e(x)}{x} \ln^2\left(\frac{\delta_e(x)}{z_{02}}\right) \sim 2\kappa^2 \quad [6]$$

For the kinds of roughness changes often studied in micrometeorology, the slope $\delta_i/x \approx 1/10$ while $\delta_e/x \approx 1/100$. Hence δ_e corresponds to the height-to-fetch requirements traditionally adopted as a rule of thumb by researchers who wish to apply one-dimensional formulas downwind of a change in surface cover.

For $\delta_i > z > \delta_e$ we have a blending region, where the velocity profile changes smoothly between $\bar{u}(z) = u_{*2}/[\kappa \ln(z/z_{02})]$ and $\bar{u}(z) = u_{*1}/[\kappa \ln(z/z_{01})]$. In this region and downwind of the immediate vicinity of the transition, the velocity and shear stress perturbations are self-preserving, that is, they can be

written as functions of a velocity scale u_0 and a dimensionless height $\eta(x) = z/\delta_i(x)$: eqns [7] and [8].

$$\Delta u(z) = \bar{u}_2(z) - \bar{u}_1(z) = \frac{u_0}{\kappa} g(\eta) \quad [7]$$

$$\Delta \tau = \tau_2(z) - \tau_{*1}^2 = [u_{*2}^2 - u_{*1}^2] h(\eta) \quad [8]$$

A good choice for the velocity scale is $u_0 = |u_{*2} - u_{*1}|$ and the functions $g(\eta)$ and $h(\eta)$ can be found by substituting eqns [7] and [8] into the equations of motion and making a closure assumption to relate $\tau_2(z)$ to $\bar{u}_2(z)$. Several theories have been developed in this way and we will encounter one of them when we consider continually changing surfaces.

Typical examples of the velocity profiles that develop following smooth-rough ($M = -4.8$) and rough-smooth ($M = +4.8$) changes are illustrated in Figure 2(a) and (b). In each case we see the internal boundary layer deepening with downstream distance and the velocity profile slowing in the smooth-rough case and accelerating in the rough-smooth case. In both cases, the lower part of the internal boundary layer is occupied by a logarithmic profile in equilibrium with the new surface, although the true depth of the equilibrium region is exaggerated by the logarithmic height scale. Measured in terms of physical distance, the equilibrium region appears to be established more slowly in the rough-smooth case, but in terms of dimensionless distance x/z_0 there is little difference between the two transitions in the rate at which equilibrium is reached.

Local Advection: Surface Stress

In Figure 3(a) and (b) are plotted measurements of surface shearing stress from the experiment that furnished the velocity profiles of Figure 2(a,b). These results are typical of those from experiments at a range of scales. Two features are noteworthy: the overshoot in stress at the transition and the rapid attainment of a new equilibrium. The overshoot phenomenon is easily explained. In the case of a smooth-rough transition, the

Figure 3 Surface shear stress development after roughness changes (data taken from Bradley (1968), see Kaimal and Finnigan (1994) for details). (a) Smooth-rough change: $z_{01} = 0.02$ mm, $z_{02} = 2.5$ mm, $M = -4.8$. (b) Rough-smooth change: $z_{01} = 2.5$ mm, $z_{02} = 0.02$ mm, $M = +4.8$. The solid line represents eqn [9] with $\delta_i(x)$ calculated using eqn [5].

air stream, traveling relatively rapidly over the smooth surface, generates a high stress on first encountering the increased roughness. As the region of decelerated flow thickens into an internal boundary layer, the velocity of the air in contact with the surface slows and the surface stress falls. In a rough-smooth transition, we see a stress undershoot with a relatively slow airstream generating lower stress when the surface roughness falls but the stress then rising as the flow accelerates.

Figure 2 The development of logarithmic velocity profiles after a roughness change (data taken from Bradley (1968) see Kaimal and Finnigan (1994) for details). (a) Smooth-rough change: $z_{01} = 0.02$ mm, $z_{02} = 2.5$ mm, $M = -4.8$. (b) Rough-smooth change: $z_{01} = 2.5$ mm, $z_{02} = 0.02$ mm, $M = +4.8$.

Although sophisticated models of the magnitude of the stress change have been developed, a simple expression can be derived by assuming that the velocity profile obeys eqn [4] with $u_* = u_{*2}$ and $z_0 = z_{02}$ for the full depth of the inner region and then obeys eqn [1] with $u_* = u_{*1}$ and $z_0 = z_{01}$ above a sharp discontinuity at $z = \delta_i$. Matching the two layers leads directly to eqn [9].

$$\frac{\tau_{02}}{\tau_{01}} = \left[1 - \frac{M}{\ln(\delta_i/z_{02})} \right]^2 \quad [9]$$

The result of eqn [9] is plotted on top of the data points in Figure 3(a) and (b) and it is clear that it performs quite well in the smooth-rough case but underestimates the stress change for the rough-smooth transition. Equation [9] relies on an accurate expression for δ_i and we have already noted that eqn [5], which is used to generate the curves in Figure 3(a) and (b) underestimates the growth rate of $\delta_i(x)$ in the rough-smooth case because it discounts the influence of the energetic upstream turbulence on the diffusion of the new internal boundary layer.

Advection on Larger Scales

The formulas we have derived above and the reasoning behind them strictly apply to internal boundary layers that are no deeper than δ_{ASL} , the depth of the atmospheric surface layer, because we have assumed that the mean velocity $\bar{u}_1(z)$ may be described by the logarithmic law. Above δ_{ASL} , both the characteristic velocity and length scales of the turbulence change. The length scale becomes $O(z_i)$, the depth of the whole boundary layer, while the velocity scale depends upon whether the boundary layer is neutrally or unstably stratified. In a neutral boundary layer, the turbulent velocity scale is u_* and, at higher levels, $\bar{u}(z)$ changes more slowly with height than in the logarithmic surface layer. More usually, the surface layer is capped by a convective mixed layer, where the turbulent velocity scale is $w_* = [g/T_0(\overline{w'\theta'})_0 z_i]^{1/3}$ with $(\overline{w'\theta'})$ the surface heat flux. In the mixed layer the mean velocity $\bar{u}(z) = U_M$ is approximately constant with height.

Inserting constant values for the turbulent velocity scale (u_* or w_*) and advection velocity ($\bar{u}(z)$ or U_M) into eqn [3], we see that we can expect $\delta_i(x)$ to grow linearly above the surface layer with a slope between $Bu_*/\bar{u}(z)$ and Bw_*/U_M as the boundary layer varies between neutral stratification and convective mixing. There are relatively few measurements in this regime, but those that exist suggest that the surface layer value $B \approx 1.25$ remains applicable.

The early attainment of a near equilibrium value of surface stress that is shown in Figure 3(a) and (b) masks the continual slow adjustment of this quantity as the internal boundary layer grows out of the surface layer. The new internal boundary layer replaces the old boundary layer when $\delta_i(x)$ equals the old boundary layer depth. This occurs at downstream distances of order $x/z_{02} = 10^6$ in neutral conditions, but possibly much less in a convective boundary layer with a weak mean wind. Current understanding of the magnitude of the geostrophic drag coefficient u_*/G , where G is the geostrophic wind speed, suggests that in the smooth-rough case illustrated in Figure 4, the early equilibrium value of $\tau_{02}/\tau_{01} \approx 3.5$ will fall to $\tau_{02}/\tau_{01} \approx 2.0$ as the new

Figure 4 Schematic drawing of the flow structure over a series of surface patches with different roughness lengths z_{0i} and streamwise extents L_i .

boundary layer attains geostrophic balance. For the neutral case, this occurs between the point at which the new boundary layer replaces the old at $x/z_0 \sim 10^6$ and $x/z_0 \sim 10^8$. Attaining a new balance between the surface drag and the geostrophic wind will also change the geostrophic departure, the angle between the surface and geostrophic wind direction. This angle will increase in a smooth-rough change and decrease in a rough-smooth change.

Patchwork Surfaces

Natural surfaces rarely consist of simple changes between two types; rather the surface cover changes continuously. To describe flow over these surfaces we generalize the concept of the internal boundary layer to define the blending height, h_B . Figure 4 illustrates a hypothetical surface consisting of a set of N patches of different surface cover, each occupying a plan area a_i with streamwise extent L_i and having roughness lengths and displacement heights z_{0i} and d_i , respectively. Over each surface an internal boundary layer grows and reaches a depth $\delta_i(L_i)$ by the end of the patch. From the definition of the internal boundary layer we know that above δ_{iMAX} , the height of the deepest internal boundary layer, the velocity profile $\bar{u}(z)$ no longer varies horizontally but attains a spatially averaged value, so we can identify the blending height with δ_{iMAX} (eqn [10]).

$$h_B = \delta_{iMAX} \quad [10]$$

If δ_{iMAX} is smaller than the depth of the surface layer δ_{ASL} , then for $\delta_{ASL} > z > h_B$ the velocity profile will be logarithmic with the form given in eqn [11], where $\langle \rangle$ here denotes an average over the x - y plane.

$$\langle \bar{u}(z) \rangle = \bar{u}(z) = \frac{\langle \tau_0 \rangle^{1/2}}{\kappa} \ln \left(\frac{z}{z_0^{eff}} \right) \quad [11]$$

A central problem over natural surfaces is to find an expression for the effective roughness length z_0^{eff} in terms of patch level roughness lengths z_{0i} and other accessible parameters such as the windspeed above δ_{iMAX} so that the area-averaged surface momentum flux $\langle \tau_0 \rangle$ can be inferred from windspeed measurements or parameterized in models that are unable to resolve the individual patches.

One approach to finding z_0^{eff} is to assume once again that the flow within each internal boundary layer, rather than being self-preserving (eqns [7] and [8]), can be represented by

logarithmic profiles with local roughness lengths and then to average the profiles across the x - y plane (eqn [12]).

$$\langle \bar{u}(z) \rangle = \left\langle \frac{\tau_{0i}^{1/2}}{\kappa} \ln \left(\frac{z}{z_{0i}} \right) \right\rangle = \frac{\langle \tau_{0i} \rangle^{1/2}}{\kappa} \ln \left(\frac{z}{z_0^{\text{eff}}} \right) \quad [12]$$

Whence we obtain

$$z_0^{\text{eff}} = \frac{\langle u_{*i} \ln(z_{0i}) \rangle}{\langle \tau_{0i} \rangle^{1/2}} \text{ and } u_{*i} = \sqrt{\tau_{0i}} \quad [13]$$

Equation [13] is not a very useful formula because we do not, in general, know the stress τ_{0i} on each patch. The simplest recourse is to ignore the correlation between stress and roughness length and to write eqn [14].

$$z_0^{\text{eff}} \approx z_0^M = \langle \ln(z_{0i}) \rangle \quad [14]$$

Because, as we have seen, z_{0i} and τ_{0i} are positively correlated, z_0^M will always be an underestimate of z_0^{eff} , but it forms a useful reference value and provides a first estimate of z_0^{eff} when the variation in roughness length between patches is small.

A more accurate formula for z_0^{eff} has been derived by exploiting the fact that the flow in the internal boundary layers making up the blending region between δ_{ei} and h_B is self-preserving and assuming that in this region a simple mixing-length expression is adequate to express the relationship between shear stress $\tau(z)$ and velocity shear $\partial \bar{u} / \partial z$. These two assumptions allow the shear stress and velocity at the blending height to be related to the local values within the thin equilibrium layer over each patch so that the value of τ_{0i} required to weight the local roughness length z_{0i} in eqn [13] can be inferred. The result is a formula for the effective roughness length that is most simply expressed as in eqn [15], where $h_{ei} = \delta_{ei}(L_i)$ and $h_i = \delta_i(L_i)$.

$$\left\langle \frac{\left[\ln \left(\frac{h_B}{z_0^{\text{eff}}} \right) + \frac{h_{ei}}{h_i - h_{ei}} \ln \left(\frac{h_i}{h_{ei}} \right) - 1 \right]^2}{\left[\ln \left(\frac{h_i}{z_{0i}} \right) + \frac{h_{ei}}{h_i - h_{ei}} \ln \left(\frac{h_i}{h_{ei}} \right) - 1 \right]^2} \right\rangle = 1 \quad [15]$$

Values for h_B , h_i and h_{ei} are readily obtained using eqns [10], [5] and [6].

Equation [15] provides a much better estimate of z_0^{eff} than z_0^M but it also starts to underestimate the momentum-absorbing capacity of a heterogeneous surface when the streamwise length scale of the patches, L_i becomes small. This is because in deriving eqn [15] it is assumed that the equilibrium value of stress, τ_{0i} , applies over an entire patch a_i and the overshoots and undershoots in stress at the roughness transitions that we saw in Figure 4 have been ignored. These strong perturbations in stress just following the change are asymmetrical, the stress increases following a smooth-rough change being generally greater than the decrease after a rough-smooth transition. By ignoring this asymmetry we can underestimate the average stress when the L_i become very small.

Larger-Scale Surface Variability

When the scale of individual surface patches L_i becomes much larger than a kilometer, the blending height will be greater than the depth of the surface layer. At much larger scales ($L_i \gg 10$ km), the new internal boundary layer will replace the

entire planetary boundary layer and the regional surface stress can be calculated by averaging the contributions of essentially independent patches. At the intermediate scale, where $10 \text{ km} > L_i > 1 \text{ km}$, the blending height will be above the surface layer and formulas based on assumptions of logarithmic velocity profiles are inappropriate. Currently there are no simple descriptions of this scale of heterogeneity. Numerical models that can accommodate the diabatic influences that are usually important above the surface layer have been used in particular cases and the average surface stress can be considered to be bounded by the values appropriate to small- and large-scale heterogeneity.

Topography

Air Flow over Isolated Hills

As we did in considering changing surfaces, we will first describe the flow over an isolated hill and then go on to consider how the boundary layer adjusts to continuously hilly terrain. We will confine our attention to hills sufficiently small that the flow perturbations they cause are confined within the boundary layer. In practice this means that the hill height H and the hill horizontal lengthscale L satisfy $H \ll z_i$ and $L \ll h^*$, where h^* , the 'relaxation length' of the boundary layer, is defined as $h^* = z_i U_0 / u_*$ or $z_i U_0 / w^*$ according to whether the flow is neutrally stratified or convectively unstable. The velocity scale U_0 is defined below. The horizontal length scale L is defined as the distance from the hill crest to the half-height point. In continuously hilly terrain it can be more appropriate to use a characteristic wavelength λ as the horizontal length scale. For sinusoidal terrain, $L = \lambda/4$.

In Figure 5 we have sketched the main features of the velocity field about an isolated hill. The figure could represent flow approaching an axisymmetric hill or a 2D ridge at right angles. Close to the surface, the flow decelerates slightly at the foot of the ridge before accelerating to the summit. In the axisymmetric case the deceleration is replaced by a region of lateral flow divergence at the foot of the hill. The wind reaches its maximum speed above the hill top and then decelerates on the lee side. If the hill is steep enough downwind, a separation bubble forms in which the mean flow reverses direction. Whether the flow separates or not, a wake region forms behind

Figure 5 Schematic drawing of the flow over a 2D ridge showing the formation of a downstream separation region when the ridge is steep enough. On an axisymmetric hill, the upwind deceleration region is replaced by a region of lateral flow divergence.

the hill with a marked velocity deficit extending for at least $10 H$ downwind.

The same information is made more concrete in Figure 6, where velocity profiles well upwind, over the hill top and in the wake are plotted. The vertical coordinate z measures height above the local surface. In Figure 6 it is made dimensionless with the inner layer height l , defined below. Upwind we have a standard logarithmic profile, but on the hill top the profile is accelerated with the maximum relative speed-up occurring quite close to the surface at $z/l \sim 0.3$. In the wake we see a substantial velocity deficit extending to at least $z = H$.

Much of the understanding we now have about the dynamics of flow over hills derives from linear theory, which assumes that the mean flow perturbations caused by the hill are small in comparison to the upwind flow. Although, strictly, linear theory is limited to hills of low slope, $H/L \ll 1$, its insights are applicable to much steeper hills. Linear theory supposes a division of the flow field into two main regions, an inner region of depth l and an outer region above, which are distinguished by essentially different dynamics (Figure 7). The balance between advection, streamwise pressure gradient, and the vertical divergence of the shear stress can be expressed in an approximate linearized momentum equation (eqn [16]).

$$U(z) \frac{\partial \Delta u}{\partial x} + \frac{\partial \Delta p}{\partial x} \sim \frac{\partial \Delta \tau}{\partial z} \quad [16]$$

Figure 6 Profiles of mean velocity observed upwind, on the crest, and in the wake region of a hill. The vertical scale is made dimensionless with the inner layer depth, l . Note the position of the maximum speed-up on the crest at $z \sim l/3$.

Figure 7 The different regions of the flow over an isolated hill, comprising: inner, middle, outer and wake layers and their associated length scales.

Δu , Δp , $\Delta \tau$ are the perturbations in streamwise velocity, kinematic pressure, and shear stress that are induced by the hill, and $U(z)$ denotes the undisturbed flow upwind of the hill. Well above the surface, perturbations in stress gradients are small and advection and pressure gradient are essentially in balance. Close to the surface an imbalance develops between these terms as the perturbation stress gradient grows. The inner layer height is defined as the level at which the left-hand side of eqn [16] equals the right-hand side.

A second interpretation of l is as the height at which the time taken for a turbulent eddy to be advected over the hill is equal to the eddy turnover time, that is, the typical lifetime before the eddy, generated by interaction with the mean flow, is dissipated. This interpretation tells us that for $z/l \ll 1$ the turbulence will be approximately in local equilibrium, that is, that production and dissipation of turbulent kinetic energy balance locally so that the relationship between the shear stress and the mean flow can be described by a mixing length or eddy-diffusivity. For $z/l \gg 1$, in contrast, the turbulence will experience rapid distortion, where changes to the turbulent stresses will depend on the cumulative straining of eddies by the mean flow as they are advected over the hill. In particular, for $z/l \gg 1$, the response of the mean flow is essentially inviscid because changes in turbulence moments have negligible effect on the mean flow. Hence, although the vertical structure of the undisturbed velocity profile $U(z)$ is entirely the result of turbulent stresses, perturbations to this profile are governed by inviscid dynamics except within the thin inner layer l (as long as $L \ll h^*$).

If the undisturbed upwind profile is taken as logarithmic, $U(z) = u_* / [\kappa \ln(z/z_0)]$, and we adopt a mixing length parametrization to relate the shear stress $\tau(x, y, z)$ to the velocity field over the hill, the first definition for the inner layer depth given above leads to an implicit expression for l (eqn [17]).

$$\frac{l}{L} \ln\left(\frac{l}{z_0}\right) = 2\kappa^2 \quad [17]$$

Equation [17] is very similar to the expression we found for the internal boundary layer height, eqn [5]. This is no accident, as yet a third interpretation of l is as the height to which new vorticity, which is generated at the surface at a rate equal to the streamwise gradient of perturbation pressure, diffuses over the hill.

The pressure field that develops over the hill deflects the entire boundary flow over the obstacle. Its magnitude is

determined, therefore, by the inertia of the faster-flowing air in the outer region and is also related to the steepness of the hill so we expect eqn [18] to hold.

$$\Delta p \sim \frac{H}{L} U_0^2 \quad [18]$$

Scaling arguments reveal that the appropriate definition of U_0 is given by eqn [19].

$$U_0 = U(h_m) \frac{h_m \ln^{1/2} \left(\frac{h_m}{z_0} \right)}{L} \sim 1 \quad [19]$$

The middle layer height h_m divides the outer region into a middle region between l and h_m where shear in the approach flow exerts an important influence on the flow dynamics, and an upper region, where the perturbations are described by potential flow. For a hill with $L = 200$ m, $u_* = 0.3$ m s⁻¹, and $z_0 = 0.02$ m, typical sizes of these scales are $l = 10$ m, $h_m = 70$ m, $U_0 = 6$ m s⁻¹ and $U(l) = 4.5$ m s⁻¹. Note that in the linear theory, the vertical extent of the regions influenced by the hill depends only on the hill length scale, L . The hill height enters only through the influence of steepness H/L on the pressure perturbation that drives all other changes in the flow field.

The pressure perturbation falls to a minimum at the hill top and then rises again behind the hill and propagates essentially unattenuated to the surface. Its scaling gives a strong clue as to why the relative speed-up peaks in the inner layer. Referring again to eqn [16], except very close to the surface the momentum balance is dominated by the pressure gradient and the advection so that $U(z)\Delta u(x, z)/L \sim (H/L)U_0^2/L$. Within the inner layer, as the background flow $U(z)$ becomes much smaller than U_0 , the velocity perturbation Δu must grow to compensate. Eventually, at the bottom of the inner layer the stress gradient dominates the momentum balance and reduces Δu so that the peak in speed-up is found at about $z \sim l/3$. The effects of this shifting balance can be clearly seen in the expression for the relative speed-up derived from linear theory, eqn [20].

$$\frac{\Delta \bar{u}(x, z)}{U(z)} = \frac{H}{L} \left[\frac{U^2(h_m)}{U(l)U(z)} \right] \zeta(x, z_0) \quad [20]$$

$\zeta(x, z_0)$ is a function that factors the precise shape of the hill and the influence of surface roughness into the equation while both the dependence of the driving perturbation pressure gradient on hill slope H/L and the amplification of the speed-up by the ratio of background velocities across the middle layer, $U(h_m)/U(l)$ is evident.

Drag Force on Isolated Hills

We are particularly interested here in the drag force exerted by the hill upon the atmosphere. This is almost entirely a result of the asymmetry in the pressure field about the hill, which results in a net form drag or pressure drag. The hill also produces a negative perturbation in the surface shear stress, equal to the balance between the increase in stress as the wind accelerates to the hill crest and the extended region of reduced stress on the downslope and sheltered wake region. Even on low hills, however, this net reduction in τ_0 is an order of magnitude smaller than the increase in form drag. Over steep hills, flow separation ensures that the pressure on the lee side of the hill

does not recover to its upstream value, leading to a net form drag, but over lower hills without separation the mechanism is more subtle.

The effect of the shear stress in the inner layer on the streamwise velocity perturbation Δu is to displace its peak value slightly upwind of the hill crest and to thicken the inner layer on the downslope side so that streamlines are not symmetrically disposed about the hill but are farther from the surface on the downslope side. The asymmetric perturbation in vertical velocity Δw that accompanies Δu is amplified by the shear in the middle layer and acts to force an asymmetric component in the pressure perturbation Δp , which is determined primarily by the flow at $z = h_m$ and above. When integrated over the hill, this asymmetry in Δp results in form drag. Put more simply, the flow well above the hill acts like an inviscid flow over a surface defined by the streamlines at the top of the inner layer and it is this 'inviscid' flow that determines the pressure field acting on the surface. From this viewpoint it is easy to see that separation will set an upper limit on flow speed-up and pressure drag because, as the hill gets steeper, the upper level flow 'sees' the hill plus separation bubble as the lower boundary condition, effectively increasing L in eqn [20] and limiting H/L .

Linear theory gives an exact expression for the drag on a 2D sinusoidal ridge of wavelength λ as eqn [21], where F_P is the streamwise pressure drag.

$$\begin{aligned} |F_P| &= 2 \left[\frac{U_0}{U(l)} \right]^4 \left[\frac{\pi H}{\lambda} \right]^2 u_*^2 \lambda \\ &= \frac{\pi^2}{2} \left[\frac{U_0}{U(l)} \right]^4 \left[\frac{H}{L} \right]^2 u_*^2 L \end{aligned} \quad [21]$$

Comparing eqns [21] and [20] we can see that the pressure asymmetry is proportional to the square of the velocity perturbation and so is proportional to the square of the hill slope H/L and to the fourth power of the shear amplification factor $U_0/U(l)$.

This formula has been successfully extended to 3D hills by generalizing the hill slope H/L to $\sqrt{A/S_h}$, where A is the frontal area of the hill and S_h its base area.

Furthermore, the same dependence of the pressure drag of a hill upon the square of the hill slope and the fourth power of the ratio of an inner to an outer level velocity scale appears to hold when we go to very steep hills well outside the compass of linear theory. Care must be taken, however, because experimental determinations of hill drag are exceedingly rare and such generalizations of eqn [21] have only been tested against numerical models so far. Nevertheless, they provide a point of departure for a consideration of the effect of hilly terrain on the whole boundary layer.

Effective Roughness Length of Hilly Terrain

Derivations of the logarithmic law in the ASL proceed by an asymptotic matching argument that applies only in the height range $z_i \gg z \gg z_s$, where z_s is a characteristic size of the surface roughness elements. When most of the drag force on the surface is due to the form drag on hills, we expect that $z_s \sim H$ and, if H is a sensible fraction of z_i , we might not expect to observe a logarithmic region at all, the ASL being squeezed between a roughness sublayer, where the flow depends on the

character of the individual hills, and the outer layer flow. Nevertheless, numerical models of flow over ranges of hills suggest that the area-averaged velocity, $\langle \bar{u} \rangle(z)$ generally does have a logarithmic dependence through a layer that can occupy a much greater fraction of the planetary boundary layer depth than the classic surface layer. The experimental evidence is less convincing, partly because area averages are very difficult to measure, but they do not directly contradict the model results.

It seems reasonable then, in analogy with eqn [11], to represent the flow over hilly terrain in the approximate range $z_i/2 > z > 2H$ as in eqn [22].

$$\langle \bar{u} \rangle(z) = \frac{u_*^{\text{eff}}}{\kappa} \ln \left(\frac{z-d}{z_0^{\text{eff}}} \right) \quad [22]$$

Hence,

$$\left(u_*^{\text{eff}} \right)^2 = \frac{\kappa^2 \langle \bar{u} \rangle(z)}{\left\{ \ln \left[(z-d)/z_0^{\text{eff}} \right] \right\}^2} = (-\langle F_P \rangle - \langle F_V \rangle) \quad [23]$$

where $\langle F_V \rangle$ is the surface friction counterpart of $\langle F_P \rangle$. Now since the perturbations in $\langle F_V \rangle$ induced by a hill are much smaller than $|F_V|$, we can write eqn [24].

$$u_*^{\text{eff}} \approx (-\langle F_P \rangle + u_*^2)^{1/2} \quad [24]$$

The area-averaged form drag is obtained by dividing eqn [21] or its 3D equivalent by S_D , the plan area of the domain under consideration, so $\langle F_P \rangle = F_P/S_D$, and we approximate the undisturbed stress u_*^2 by assuming that it can be related to the area-averaged velocity at h_m through the undisturbed roughness length z_0 (eqn [25]).

$$u_*^2 = \frac{\kappa^2 \langle \bar{u} \rangle^2(h_m)}{\ln(h_m/z_0)} \quad [25]$$

This is not a bad assumption when $H \ll h_m$, while over steeper hills the pressure drag term is dominant and we can ignore $\langle F_V \rangle$ for all practical purposes. Equations [23], [24] and [25] can now be combined with [21] or its 3D equivalent to give an expression for the effective roughness length of a hilly landscape. We can take the displacement height d as the average level of the terrain. Since we should not apply eqn [22] too close to $z = H$, the precise specification of d is not critical.

The resulting expression for z_0^{eff} has been compared to mathematical models of the whole boundary layer and of the surface layer and it corresponds to within better than 15% for slopes $\sqrt{A/S_h} < 0.5$. Comparison with field data is more difficult, but the expression matches the available data reasonably well. z_0^{eff} is an increasing function of slope $\sqrt{A/S_h}$ for low to moderate slopes and z_0^{eff} for a range of 2D ridges is substantially larger than for a range of close-packed 3D axisymmetric hills of the same wavelength, a result confirmed by numerical model studies that give values of $z_0^{\text{eff}2D}/z_0^{\text{eff}3D}$ between 3 and 6. An idea of the actual change that hills induce in the effective roughness of a natural surface can be gained by noting that, for 2D ridges with $z_0 \approx 0.1$ m and $\sqrt{A/S_h} \approx 0.5$, we find that $z_0^{\text{eff}}/z_0 \approx 15$, while for close-packed 3D axisymmetric hills with the same z_0 and A/S_h , we find $z_0^{\text{eff}}/z_0 \approx 4$.

Summary

We have seen both similarities and differences between boundary layers over two kinds of complex surface. Over continuously changing horizontal surfaces we observe a blending region where turbulence properties and scaling depart from standard equilibrium ASL forms. The depth of this zone is related to the size of the surface patches and to the rate at which turbulence can diffuse information about the surface changes vertically. For sufficiently large patches the whole boundary layer readjusts to the new surface. Except very close to the edges of distinct patches, pressure effects are negligible but, if the surface is covered with scattered bluff objects like wind-breaks or buildings, these can be responsible for a large fraction of the total drag of the landscape.

Over natural hilly landscapes we also find a region of altered mean flow extending up to $z \sim L$, where L is the horizontal length scale of the hills, but the depth of this region is determined by the pressure field that develops around the hill. Turbulent diffusion, in contrast, affects only a shallow surface layer. Increased momentum absorption by the hills is almost entirely the result of pressure drag and, even for very shallow hills, this substantially exceeds the drag of a flat surface with the same surface texture.

Introduction

The boundary layer is that layer of a fluid that is directly influenced by the surface. For the convective boundary layer (CBL), the surface influence is felt through rising, buoyant air currents. Over land, the air currents are buoyant because they have been warmed by the surface. Over the ocean, the air currents are buoyant from a combination of warming at the surface, and evaporation of water, which lightens the resulting gas mixture because of its lower molecular weight. These currents rise and cool dry-adiabatically, until they lose their vertical momentum and buoyancy through mixing and reaching heights where the environmental air is warmer. Between the rising currents, air sinks and warms dry-adiabatically. The depth of the dry convective boundary layer is thus determined by the temperature of the updrafts and the change of temperature with height in the environment. Within the CBL, the vertical motions reach values of $\pm 1\text{--}2\text{ m s}^{-1}$, strong enough to support soaring birds or to make flying in aircraft uncomfortable.

Aircraft, radar, and lidar observations of the convective boundary layer suggest a flow structure as shown in [Figure 1](#). Small buoyant elements rise from the warm surface. Some (plumes) remain attached to the surface, others (bubbles) detach as they grow vertically. We will use the word 'thermals' to describe both types of buoyant element. As the thermals rise, they merge. Large eddies, which span the depth of the convective boundary layer, collect the smaller thermals into their upwelling regions. The top of the convective boundary layer is uneven – typically higher where large-eddy motions are upward. While plumes or bubbles can occur anywhere, on average there are fewer thermals in the downwelling portions of the larger eddies, which are thus less turbulent than the upwelling regions. The interfacial or entrainment layer lies within the range of heights occupied by both the CBL air and the atmosphere above at different locations or times.

The convective boundary layer over land forms and dies during the daylight hours ([Figure 2](#)) of sunny days. Starting at sunrise, air rising from the warming ground breaks down the nocturnal inversion. Within 2–3 hours, the CBL grows to about 100 m. Rapid growth typically continues until the CBL reaches a depth of 1–2 km about 11:00 h to 12:00 h, local time. The CBL is in a quasi-steady state for the next 4–5 h, with a slowly changing depth. A few hours before sunset, the ground begins to cool, forming a stable layer near the ground. Plumes no longer rise from the ground, and the turbulence decays in the dry adiabatic layer above. This layer, decoupled from the ground, is often called the residual layer.

We live within the CBL, and its evolution is closely tied to the environmental conditions we experience. Vertical mixing decreases air pollution near the ground from nearby sources, but it can also transport to the ground pollution transported above the CBL from more distant sources. On average, the wind speeds over land are lowest during the night, when the stable nocturnal inversion decouples the surface from the wind overhead; and are largest during the day, when the momentum from above is mixed downward by the CBL. When the CBL grows deep enough for rising thermals to reach their condensation levels, clouds form. The evolution of cloud formation and the depth of the boundary layer affects the maximum surface temperature and the formation of showers.

Mean Vertical Structure

Horizontally averaged profiles of CBL potential temperature (Θ), moisture (Q), and the wind components U and V are controlled by the strong vertical mixing ([Figure 3](#)). The wind components U and V are in a right-handed coordinate system with U parallel to the surface-layer wind and positive downwind. In the dry CBL, temperatures of the rising and sinking air parcels closely follow the dry-adiabatic lapse rate, 9.8 K km^{-1} .

Figure 1 Idealized cross-section of the convective boundary layer. Eddies are outlined. Broad arrows denote flow in large eddies; small arrows denote flow in smaller eddies.

Figure 2 Diurnal variation of CBL over land.

Thus it is convenient to use potential temperature, which is conserved during dry-adiabatic processes, to describe the thermal stratification:

$$\theta = T \left(\frac{1000}{p} \right)^{R/c_p} \quad [1]$$

In eqn [1], which is derived from the first law of thermodynamics and the hydrostatic relation, p is pressure, T is temperature (K), R is the gas constant, and c_p is the specific heat at constant pressure for air. Similarly, the water-vapor quantities conserved in the absence of condensation or evaporation are used to define the mean state of the CBL, namely specific humidity ($q = \rho_w/\rho_a$, where ρ_w is the mass density of water

vapor and ρ_a is the mass density of air) or mixing ratio (ρ_w/ρ_d , where $\rho_d = \rho_a - \rho_w$ is the mass density of dry air).

The convective boundary layer can be divided into three parts (Figure 3), the mixed layer (heights z_s to h_1), where Θ , Q , U , and V are nearly constant, the surface layer (heights less than z_s , where Θ and Q decrease and U increases rapidly with height, and the entrainment or interfacial layer (heights h_1 to h_2), where all four variables change rapidly with height from their mixed-layer values to those of the atmosphere above. In this layer, the vertical changes in Θ , Q , U , and V reflect the fractional area at each height occupied by turbulent convective boundary layer air. The inversion height z_i is drawn roughly halfway through the entrainment layer, where vertical gradients

Figure 3 Idealized profiles of horizontally averaged potential temperature Θ , specific humidity Q , and wind components U and V in the convective boundary layer. Values increase to the right. $V \approx 0$ in the CBL.

are a maximum. Above the interfacial layer, the stratification is that of the free atmosphere.

If the water-vapor content is substantial, as is common over the tropical oceans, the stratification of the CBL is often defined in terms of the virtual potential temperature, θ_v , defined by:

$$\theta_v = \theta(1 + 0.61q) \quad [2]$$

since water vapor contributes significantly to buoyancy ($= (g/\Theta_v)(\theta_v - \Theta_v)$), which dominates CBL growth and mixing. In eqn [2], specific humidity is in units of g kg^{-1} .

Momentum is likewise well mixed through most of the CBL. The momentum is determined by a balance between the pressure gradient force $-(1/\rho_a)\nabla P$, the Coriolis force $f\mathbf{k} \times \mathbf{V}$, and surface friction Fr . At equilibrium

$$f\mathbf{k} \times \mathbf{V} = -\frac{1}{\rho_a}\nabla P + Fr \quad [3]$$

The wind vector $\mathbf{V}$ is parallel to the isobars to a close approximation above the CBL, where friction is negligible. Within the CBL, the Coriolis force $f\mathbf{k} \times \mathbf{V}$ is reduced as a result of frictional slowing of the wind, and the air flows down the pressure gradient toward lower pressure. In the northern hemisphere CBL, the mixed-layer wind U flows in a direction ~ 20 – 30 degrees to the left of the wind above the CBL. The rotation of the wind from the surface-layer direction to the free atmosphere direction is concentrated in the entrainment layer.

Vertical Fluxes in the CBL

The Mixed Layer

To describe the behavior of the turbulent air in the mixed layer, we separate out the fluctuations (denoted by primes) from the means, denoted by upper case. Thus, for specific humidity,

$$q' = q - Q$$

where Q is the average of q at a given height. The vertical flux of q , $\overline{w'q'}$ at a height z is given by the average of the product of the fluctuating vertical velocity w' and q' ,

$$\overline{w'q'}(z) = \frac{1}{N} \sum_{i=1}^N w'_i(z) q'_i(z) \quad [4]$$

where N is the number of observations. Positive values of $\overline{w'q'}$ indicate upward transport of water vapor (or downward transport of dry air).

In the mixed layer, the profiles of the vertical fluxes of θ_v , q , and u , are linear (Figure 4). The vertical q -flux is depicted decreasing with height, but $\overline{w'q'}$ can also increase with height. The decrease of $\overline{w'\theta'_v}$ with height to about -0.2 times the surface flux at z_i has been commonly observed. From eqn [2], the profile of θ -flux $\overline{w'\theta'}$ should also be linear:

$$\frac{\partial \overline{w'\theta'}}{\partial z} = (1 + 0.61Q)^{-1} \left(\frac{\partial \overline{w'\theta'_v}}{\partial z} - \Theta \frac{\partial \overline{w'q'}}{\partial z} \right) \quad [5]$$

Over the tropical oceans in fair weather, $\overline{w'q'}$ is large and $\overline{w'\theta'}$ is small or even negative through most of the CBL, particularly if the humidity flux remains large at the CBL top. This is illustrated in Figure 5, which is based on data from the Global Atmospheric Research Programme's (GARP) Atlantic Tropical Experiment (GATE). On Day 253 (bottom), the temperature flux is negative through half the CBL. When this profile is combined with the humidity flux profile using eqn [5], the result is a $\overline{w'\theta'_v}$ -profile close to the idealized profile shown in Figure 4. On Day 258 (top), the temperature flux is so small that the humidity flux accounts for most of the virtual-temperature flux, whose profile again resembles that in Figure 4.

The temperature and moisture fluxes are typically expressed in K m s^{-1} and $\text{g kg}^{-1} \text{m s}^{-1}$, as in Figure 5 or, when the energy balance is of interest, in terms of sensible heat flux

$$H = \rho_a c_p \overline{w'T'} \approx \frac{T}{\Theta} \rho_a c_p \overline{w'\theta'}$$

Figure 4 Idealized vertical profiles of the vertical flux of virtual-potential temperature flux $\overline{w'\theta'_v}$, specific humidity, $\overline{w'q'}$, and the u -momentum flux $\overline{u'w'}$ (parallel to the mean surface-layer wind).

Figure 5 Vertical fluxes of T , T_v , and q , for two days in GATE with different q -flux and T -flux profiles. Note that the shape of the T_v -flux profile remains the same. Figure adapted from Nicholls and LeMone, 1980. *Journal of Atmospheric Science* 37: 2051–2067.

and latent heat flux $LE = \rho_a L_w \overline{w'q'}$ where L_w is the latent heat of vaporization. H and LE have units of $W m^{-2}$. The maximum values of $H + LE$ in fair weather rarely exceed the incoming solar radiation. A summer noontime mid-latitude value of $\sim 1000 W m^{-2}$ is equivalent to $\overline{w'T'} \sim 0.8 K m s^{-1}$ or $\overline{w'q'} \sim 0.3 g kg^{-1} m s^{-1}$ for $\rho_a = 1.27 kg m^{-3}$, $c_p \sim 1000 m^2 s^{-2} K^{-1}$ and $L_w = 2.5 \times 10^6 m^2 s^{-2}$. Typical fair-weather values of temperature fluxes over the ocean range from less than $0.01 K m s^{-1}$ over the tropical and subtropical oceans in fair weather to $0.20 K m s^{-1}$ for cold air flowing over warm water; over land at noontime values reach $0.4 K m s^{-1}$. Water vapor fluxes over the ocean lie in the range 0.015 – $0.05 g kg^{-1} m s^{-1}$ in the fair-weather tropical boundary layer to $0.25 g kg^{-1} m s^{-1}$ for cold air flowing over warm water; noontime values over land reach $0.25 g kg^{-1} m s^{-1}$.

The linear flux profiles for θ_v , q , u , and v can be shown to be consistent with their mean profiles through their tendency equations. The tendency equation for a quantity C takes the form:

$$\frac{\partial C}{\partial t} \approx -\frac{\partial}{\partial z} \overline{w'C'} - V \cdot \nabla C + S + \sum F_i \quad [6]$$

where $\partial C / \partial t$ is the local time tendency, $-(\partial / \partial z) \overline{w'C'}$ is the change in C due to vertical divergence of the vertical c -flux, $-V \cdot \nabla C$ is advection, S represents sources and sinks, and $\sum F_i$ represents forces (for $C =$ momentum). The horizontal divergence of horizontal fluxes is negligibly small in the fair-weather CBL and is neglected. For Θ_v and Q , $\sum F_i = 0$. If there is no horizontal advection or sources/sinks (approximately true with no clouds and if radiative effects are negligible)¹ then

$$\frac{\partial (\Theta_v, Q)}{\partial t} \approx -\frac{\partial}{\partial z} \overline{w'(\theta_v, q)'} \quad [6a]$$

¹ Typical maximum warming or cooling from radiation is of the order of $0.05 K hr^{-1}$ in the unpolluted CBL.

From eqn [6a], a linear flux profile is consistent with the constant mean profiles in Figure 3, since $\partial C / \partial t$ must be independent of height for C to remain independent of height.

Equations [3] and [6] can be combined for momentum to obtain, neglecting advection

$$\frac{\partial U}{\partial t} \approx -\frac{1}{\rho_a} \frac{\partial}{\partial z} \overline{\rho_a u'w'} + fV - \frac{1}{\rho_a} \frac{\partial P}{\partial x} \quad [6b]$$

In the absence of horizontal temperature gradients, the pressure gradient force $-(1/\rho_a)(\partial P / \partial x)$ is nearly constant with height. U and V are nearly constant in the mixed layer from Figure 3 and hence $\partial U / \partial t$ must be nearly constant with height. Thus $-(1/\rho_a)(\partial / \partial z)(\overline{\rho_a u'w'})$ is constant with height, and the profile of $u'w'$ is nearly linear. Figure 6 shows $u'w'$ and $v'w'$ as a function of height based on a Large Eddy Simulation (LES) and observations (for u only) for constant $(1/\rho_a)\nabla P$. Surface values of $u'w'$ are of the order of $-1 \times 10^{-6} U^2 m^2 s^{-1}$, with higher values over rougher surfaces. The vertical flux of u -momentum remains small.

Comparison of Figure 3 and Figure 4 shows that vertical fluxes are large even where the mean vertical gradient is zero. This results from the mixing elements extending through the CBL (Figure 1). For example, updrafts ($w' > 0$) carry low values of u ($u' < 0$) upward from near the surface, and downdrafts ($w' < 0$) carry high values ($u' > 0$) from near the top of the CBL, resulting in the observed negative vertical flux of u -momentum. When vertical fluxes are determined by vertical gradients over a deep layer rather than locally, we call this nonlocal transport or nonlocal mixing.

The Surface Layer

Vertical gradients of Θ , Q , U , and V are substantial in the surface layer. The behavior of the surface layer has been

Figure 6 LES vertical fluxes of u and v for $-(1/\rho)\nabla P$ constant with height and CBLs with $-z_i/L$ ranging from 7.7 (I77) to 0.3 (I03). IN represents the neutral boundary layer. Circles are data from north of Puerto Rico ($-z_i/L \sim 2$). Figure adapted from Brown and Grant, 1997. *BLM*, 84: 1–22; with data from Pennell and LeMone, 1974. *Journal of Atmospheric Science* 31: 1308–1323.

successfully described in terms of similarity theory, for which the relevant physical parameters are identified and then combined in a dimensionally consistent way. For example, under neutral stability in the atmosphere, where viscosity is negligible, it can be assumed that the vertical shear of the mean wind is a function related to distance from the ground and surface stress $u_*^2 = ((u'w')_0^2 + (v'w')_0^2)^{1/2} \approx (u'w')_0$ for u defined as parallel to the mean surface-layer wind. That is,

$$\frac{\partial U}{\partial z} \propto \frac{u_*}{z} \quad [7]$$

where u_* is called the friction velocity. Hence $U \sim \ln(z/z_0)$, where z_0 is the height at which $U = 0$. Typical values of z_0 over open land are of the order of 10^{-2} m.

Monin–Obukhov similarity theory includes the effects of buoyancy as well as stress. Thus the relevant parameters are u_* , g/T_v , and virtual temperature flux, $\overline{w'T'_v}$. The scaling height in the surface layer is the Monin–Obukhov scaling length, L , given by:

$$L = -\frac{u_*^3}{(kg/T_v)\overline{w'T'_v}} \quad [8]$$

where g is the acceleration of gravity, and k is the von Karman constant (about 0.4). Within the surface layer, u_* and $\overline{w'T'_v}$ are assumed constant. The depth of the surface layer is typically of the order of $0.1z_i$.

From dimensional reasoning and numerous field measurements, the profiles of a quantity $c = \theta, q$, or u in the surface layer are represented in the form:

$$C = C_0 + c_* \left[\ln \frac{z}{z_c} + \Psi_c \left(\frac{z}{L} \right) \right] \quad [9]$$

where $\Psi_c(z/L)$ is a stability correction that increases as surface buoyancy flux increases ($-L$ decreases), and $c_* \equiv \overline{w'c'}/u_*$. The height z_c is defined so that $C(z_c) = C_0$, the value of C just above the surface. Typical values of z_c are of the order of a few centimeters or smaller.

The Entrainment Layer

The entrainment layer is occupied by both boundary layer and free-atmosphere air, and the virtual temperature flux is negative. The varying CBL top is not a material surface: the more-turbulent air tends to engulf the air above, incorporating it into the CBL. Downward motion at the edge of thermals can draw free-atmosphere air downward into the CBL, where it is mixed in. Strong shear at the top of the CBL can generate shear-buoyancy waves which can break and mix the air at the interface. This mixed air, being less buoyant than free-atmosphere air, can then be more easily mixed downward into the CBL.

The growth of the CBL is determined by how fast new air is engulfed into the CBL, itself a function of the energy of the engulfing eddies, the resistance of the free-atmosphere air to engulfment (a function of the virtual temperature difference ΔT_v between the CBL and the free atmosphere), and the mean largescale vertical motion at the CBL top. For simplicity, we collapse the entrainment layer to zero thickness so that $h_1 = h_2 = z_i$. For this simple case,

$$\frac{\partial z_i}{\partial t} = -\frac{(\overline{w'T'_v})_{z_i}}{\Delta T_v} + W_{z_i} \quad [10]$$

Figure 7 Vertical velocity variance $\overline{w'^2}$, normalized by CBL velocity scale w_*^2 , from GATE and AMTEX aircraft data. Best-fit quadratic from Lenschow, et al., 1980.

In eqn [10], $-(\overline{w'T'_v})_{z_i}/\Delta T_v$ is the entrainment velocity (w_e), or rate of growth of the CBL in the absence of subsidence (W_{z_i}). $(\overline{w'T'_v})_{z_i}$ varies with the energy expended in entrainment; ΔT_v is related to the stratification of the air above the CBL. It is commonly assumed that

$$(\overline{w'T'_v})_{z_i} \approx -0.2(\overline{w'T'_v})_0 \quad [11]$$

and this is widely supported by observations.² However, the coefficient might be much larger than -0.2 if there is large vertical shear of the horizontal wind at the CBL top.

Turbulence Structure in the CBL

In his 1972 paper describing the first large eddy simulation of the convective boundary layer, Deardorff found that the proper scaling parameters for the CBL are

$$w_* \equiv \left(\frac{g}{T_v} (\overline{w'T'_v})_0 z_i \right)^{1/3} \quad [12a]$$

$$\theta_v^* \equiv \frac{(\overline{w'T'_v})_0}{w_*} \quad [12b]$$

where z_i is defined in Figure 3.

The success of the Deardorff scaling velocity w_* is illustrated in Figure 7, which combines data from field programs in very different environments, GATE and the Air Mass Transformation Experiment (AMTEX). For AMTEX (6 days), w_* averaged 1.72 m s^{-1} , with a range from 1.06 to 2.51 m s^{-1} ; for GATE (4 days of data), w_* averaged 0.53 m s^{-1} , with a range from 0.50 to

² It is important that virtual temperature be used here. If the humidity flux is substantial, $-(\overline{w'T'_v})_{z_i}$ is typically much larger than $0.2(\overline{w'T'_v})_0$, as shown in Figure 5.

Figure 8 Profiles of $\overline{q'^2}/q_*^2$, $\overline{\theta'^2}/\theta_*^2$, from AMTEX aircraft data. Adapted from Lenschow, et al., 1980. Journal of Atmospheric Science 37: 1313–1326.

0.59 m s^{-1} . This amounts to a factor of 25 range in normalizing factors. The outlined inverted triangles are for GATE days with enhancement of vertical velocities originating from release of latent heat in active cumulus clouds. Normalization with w_* does not account for this process, so it is not surprising that these points are associated mostly with higher vertical velocities than the normalized curve would predict.

Similarly, $\overline{q'^2}/q_*^2$, where $q_* = \overline{w'q'}/w_*$, and $\overline{\theta'^2}/\theta_*^2$ both collapse onto a curve whose shape is based on local free convection similarity arguments, for which z , z_i , g/T_v , and $\overline{w'T'_v}$ are the relevant variables, in the lower CBL (Figure 8), at least for $z = z_i < 0.1$, but not for the upper CBL, especially for $\overline{q'^2}/q_*^2$.

The deviations of the normalized q - and θ -variances from the curves in Figure 8 are related to entrainment processes at the top of the CBL. The deviations can be accounted for if one assumes a separation of the corresponding fluxes into 'top-down' fluxes associated with entrainment processes, which decrease linearly from a maximum value at z_i to zero at the surface, and 'bottom-up' fluxes, which decrease linearly from the surface flux to zero at z_i . The variance of a scalar c can be written:

$$\overline{c'^2} = \overline{c_t'^2} + 2\overline{c_t'c_b'} + \overline{c_b'^2} \quad [13]$$

where the c_t -fluctuations are associated with 'top-down' processes, and c_b -fluctuations with 'bottom-up' processes. Each component can be normalized using the corresponding flux:

$$f_t = \overline{c_t'^2} \left[\frac{w_*}{(\overline{w'c_t'})_1} \right]^2 \quad [14a]$$

$$f_b = \overline{c_b'^2} \left[\frac{w_*}{(\overline{w'c_b'})_0} \right]^2 \quad [14b]$$

$$f_{tb} = \overline{c_t'c_b'} \left[\frac{w_*^2}{(\overline{w'c_t'})_1(\overline{w'c_b'})_0} \right] \quad [14c]$$

where $(\overline{w'c_t'})_1$ is the top-down scalar flux at the CBL top, $(\overline{w'c_b'})_0$ is the bottom-up scale flux at the surface, and f_t , f_b , and f_{tb} are dimensionless functions that can be determined using a large

eddy simulation (LES). From eqns [13] and [14], the nondimensional variance of θ can be written:

$$\frac{\overline{\theta'^2}}{\theta_*^2} = f_b + 2Rf_{tb} + R^2f_t \quad [15]$$

where $R = \overline{w'\theta'_1}/\overline{w'\theta'_0}$ accounts for the top-down processes. The resulting function is in better agreement with AMTEX data (Figure 9).

Large Eddy Structure in the CBL

Figure 1 shows a CBL inhabited by a spectrum of eddies ranging in size from tiny plumes near the surface to large eddies

Figure 9 Profile of $\overline{\theta'^2}/\theta_*^2$ from AMTEX aircraft data. LES-derived curves accounting for top-down and bottom-up processes are drawn for a plausible range of $R = \overline{w'\theta'_1}/\overline{w'\theta'_0}$ based on AMTEX data. From Wyngaard and Moeng, 1989. Journal of Atmospheric Science 14: 2313–2330.

Figure 10 Horizontal variation of CBL large-eddy structure with $-z_i/L$: (a) $-z_i/L$ near 1.5, (b) $-z_i/L$ near 10, (c) large $-z_i/L$ (near-calm winds). Shading indicates upwelling regions at a level in the upper half of the CBL; air sinks between. Small arrows illustrate near-surface flow converging into upwelling regions; flow diverges at CBL top. For rolls, each upwelling region is fed by two counter-rotating vortices. The large arrows represent the wind vector above the CBL.

spanning the CBL, with horizontal scale (updraft+downdraft) of the order of 1.5–3 times the CBL depth. Smaller eddies and turbulence are concentrated in the large-eddy updrafts.

The variation of large-eddy structure with $-z_i/L$ is illustrated in **Figure 10**. Roll vortices occur in the CBL for $-z_i/L$ between some small but unknown positive value and ~ 25 ,³ with more cellular or random convection at higher values. The rolls (**Figure 10(a)**) are horizontal counter-rotating helical circulations that extend through the CBL. They are oriented close to parallel to the mean CBL wind, or between 15 and 30 degrees to the left of the geostrophic wind (or wind above the CBL) in the middle latitudes of the northern hemisphere. Lines of cumulus clouds, or ‘cloud streets’, sometimes lie above their upwelling regions. The small angle between rolls and the mean CBL wind means that it can take a half-hour, an hour, or even longer for a roll to pass over a given point on the surface. As $-z_i/L$ increases, the rolls become more three-dimensional, looking more like lines of cells (**Figure 10(b)**). The relatively slow advection time for rolls makes it possible to separate them from the other large eddies using instruments fixed to the ground, even though the large eddies may have horizontal scales comparable to that of rolls in the cross-wind direction. The linear structures disappear at high $-z_i/L$, and convection becomes more cellular or random (**Figure 10(c)**).

The dependence of large-eddy structure on $-z_i/L$ has been revealed by observational studies and LES. The higher ratios are associated with observational studies; LESs give upper limits around 1.5–2.6. This is partially a result of the three-dimensionality of rolls at higher $-z_i/L$. With limited horizontal resolution and distortions resulting from periodic boundary conditions, such rolls would be hard to identify in an LES. Further, the definition of ‘roll’ becomes ambiguous as they

become more three-dimensional, even in observations. Finally, rolls formed over land in the early morning (small $-z_i/L$) often persist as $-z_i/L$ gets large.

Departures from the Idealized CBL

The CBL profiles presented apply strictly to a quasisteady-state boundary layer in horizontally homogeneous conditions with negligible influence from clouds. Clouds were present when AMTEX (stratocumulus) and GATE (cumulus) measurements shown in **Figure 5** were taken, but their thickness or coverage was too small to produce a measurable effect (the open triangles representing the exceptions). Over land, strong diurnal variation restricts ‘quasi-steady-state’ CBLs to roughly 4–5 h starting around solar noon. Further, terrain, surface vegetation, and soil moisture are rarely homogeneous, leading to uneven heating, evaporation, and stress. The marine CBL in fair weather is close to steady state; winds of a few m s^{-1} can mix the upper levels of the ocean sufficiently that the diurnal variation of temperature at the surface is less than 1 K, with correspondingly small changes in the CBL. Even in near-calm fair weather conditions, the diurnal variation of sea surface temperature rarely exceeds 2.5 K. Cloudless marine boundary layers are rare, but the subcloud layer follows CBL scaling in marine CBLs topped with small cumulus and relatively weak inversions. Marine CBLs with strong surface heating and some shallow stratocumulus whose vertical growth is halted by a strong inversion scales with z_i which also corresponds to cloud top. These two types of CBL remain sufficiently steady over several hours that they can be well sampled. Thus it is not surprising that AMTEX (some stratocumulus) and GATE (clear to small cumulus) data are commonly used to test CBL similarity theories and parametrization schemes.

Because nonideal fair weather CBLs are so common, some of the features to expect are summarized.

³ The ratio $u_*'/w_*' = (-0.4L/z_i)^{1/3}$ is also used to separate rolls from more three-dimensional CBL convection.

Baroclinic CBLs

The wind profiles in the quasi-steady-state baroclinic CBL remain constant within the mixed layer. From eqn [6b], a linearly varying horizontal pressure gradient with height will be reflected in quadratic vertical profiles of $\overline{\rho_a u' w'}$ and $\overline{\rho_a v' w'}$.

Rapidly Entraining CBLs

Such CBLs occur during the morning in fair weather, or when strong surface heating is combined with a weak temperature inversion at the CBL top. Mean profiles of specific humidity and wind vary with height in the mixed layer under such conditions. However, the profile of Θ (or Θ_v in humid conditions) remains nearly constant.

CBLs with Nonprecipitating Cumulus

Once clouds become deep enough, latent heating or interaction of the clouds with vertical shear will develop vertical pressure forces that enhance the exchange of air across the cloud–subcloud layer interface. This increases $\overline{w'^2}$ at mixed-layer top as in Figure 7; the resulting vertical mass exchange across the cloud–subcloud layer interface also produces vertical variation in Q , U , or V and enhances fluxes and variances, especially in the upper CBL. Surprisingly, GATE data showed that the shape of the virtual-temperature flux profile did not change in the presence of deeper cumulus clouds. Deeper clouds can also ‘break up’ roll vortex circulations.

CBLs Over Nonhomogeneous Surfaces

Moistened surfaces with growing vegetation produce more vapor flux and less heat flux than dry surfaces with dormant vegetation or concrete. The fluxes may ‘blend’ or lose their clear relationship to individual surface features at a certain height if land use variability takes place at small scales. However,

larger-scale nonuniformities (>10 km) can produce mesoscale variability, with more vigorous turbulence and higher z_i over warmer surfaces, and less vigorous turbulence and lower z_i over cooler surfaces. Mesoscale circulations with upwelling regions over warmer surfaces may also occur in light winds, but these are difficult to document. Elevated terrain and slopes facing the sun are favored places for updrafts in light winds. Flow is deflected over and around hills, locally producing stronger than ambient winds and turbulence.

Synopsis

Microclimatology is concerned with the study of the processes by which the local surface properties affect the lowest layer of the atmosphere. Often the latter refers to the so-called roughness sublayer, but in some cases attention is more properly limited to the so-called canopy layer or then, conversely, the whole surface layer. Microclimates are described in terms of climatic variables, their temporal and vertical variability, as established by the balance equations that govern the exchange of radiation, heat, water, and other atmospheric constituents.

Introduction

The word 'climate' stems from the Greek *klíma* (slope, zone), with its roots in *klínein* (to slope), and originally denoted 'a zone of equal latitude,' thus referring to the effects of latitude on the availability of solar energy. In fact, on a global scale the climate is above all determined by the latitudinal and seasonal distribution of incoming solar radiation as given by Earth's orbital parameters.

On very small scales, however, the climate is primarily shaped by the local surface properties that control the exchange of radiation, energy, momentum, and water between the ground and the atmosphere. The *microclimate* of a particular location can hence be defined as the collection of statistics describing the thermal and dynamical conditions prevailing in the atmospheric layer directly affected by the underlying surface. Accordingly, 'descriptive microclimatology,' can be identified as the study of the long-term average and typical variability of climate variables in the lowest layer of the atmosphere, while 'physical microclimatology' can be defined as the study of the processes by which the lowest layer of the atmosphere responds to surface boundary conditions.

As is customary in climatology, the various aspects that concur in creating the microclimate of a particular location are identified with a number of so-called climate variables. Common climate variables include radiation, temperature, humidity, wind speed, and pressure (density), but, depending on the research focus, other variables need to be taken into account. For example, the health and comfort of the ever-increasing number of people living in cities are directly related to the concentration and distribution of air pollutants, which are therefore required to characterize the microclimate of these particular environments.

The surface properties determining a microclimate are seldom constant in time. Long-term variations may arise naturally or as a consequence of human-induced changes in land use. At the seasonal scale, variations in surface properties may be brought about by the presence of a snow cover or through the life cycle of plants. Short-term variations may, for example, be caused by the dynamic effects of the wind on the structure of the surface elements. Ultimately, it is this variability in surface properties that, along with the variability of the large-scale atmospheric forcing, is responsible for the

characteristic temporal patterns observed in microclimatic records.

The Lowest Layers of the Atmosphere

The atmospheric layer affected by the local surface properties is called the 'planetary boundary layer' (PBL). It has a characteristic depth (z_i) on the order of 1000 m and can be divided into an upper or outer layer (the uppermost 90%) and an inner or surface layer (SL) (the lowest 10%) (Figure 1). However, a *direct* influence of the surface characteristics on the atmospheric state is observed only in the *lowest part* of the SL, in the immediate vicinity of the roughness elements. If this layer of influence has any discernible thickness, it is because of a non-negligible vertical extension of the 'roughness elements' (stones, vegetation, tress, and buildings). Therefore, this layer is usually called the 'roughness sublayer.' The upper part of the SL is then referred to as the 'inertial sublayer.' Over a relatively smooth surface such as short grass or sand, the roughness sublayer becomes very thin and the inertial sublayer is often associated with the entire SL (Figure 1).

Based on these considerations, 'microclimatology' can also be defined as the study of the climatic state of the roughness sublayer or specific entities therein, even though the notion is most often extended to the examination of the entire SL or even PBL. Micrometeorology is then the study of the dynamics and thermodynamics of the SL or PBL.

The Roughness Sublayer

In the roughness sublayer, the flow is affected by the individual roughness elements and hence is fully three-dimensional in nature. The upper boundary of the roughness sublayer, z_r , is the level at which the horizontal variability associated with the roughness elements vanishes and the flow properties become horizontally homogeneous. Properly scaled 'profiles' of either mean flow characteristics or turbulence statistics will then merge to one curve whose shape is characteristic for the underlying surface. The depth of the roughness sublayer depends on the height and distribution of the roughness elements. For most surfaces, $2z_h < z_r < 5z_h$ covers the range of estimates, where z_h is the *average* height of roughness elements.

Figure 1 Conceptual sketch and terminology for the lowest layers of the atmosphere over a rough surface. Note the logarithmic height scale. Level z_i refers to the boundary layer height, z_r to the height of the roughness sublayer, and z_h to the (average) height of roughness elements.

The Canopy Layer

The lowest part of the roughness sublayer is the canopy layer. It ranges from the surface to z_h . In this layer, form (or pressure) drag and viscous drag on any individual roughness element are both significant and lead to a retardation of the flow. In addition, the material and orientation of the obstacles give rise to large variations in the energy balance, primarily through variations in the radiation balance, and also as a result of the distribution of sources and sinks of sensible heat, water vapor, or trace gases.

Figure 2 shows the height ranges covered by the roughness sublayer and its lower part, the canopy layer, in dimensionless

Figure 2 Sketch of the vertical extension of the various layers over rough surfaces and their variation with the nondimensional quantities z/z_i and z_i/z_h . Here, z denotes the (physical) height, z_i refers to the boundary layer height, and z_h is the (average) height of roughness elements. A value of $z_r/z_h = 3$ is assumed for the height of the roughness sublayer. The arrows labeled with 'city,' 'forest,' 'crop,' and 'short grass' are based on typical values for the height of the roughness elements z_h and the boundary layer height z_i . Redrawn from Rotach, M.W., 1999. On the urban roughness sublayer. *Atmospheric Environment* 33, 4001–4008.

form. Arrows indicate how surfaces covered with short grass, crops, trees, and houses, respectively, fit into this scheme. It can be seen that the vertical range, to which the study of microclimate is confined, can extend up to several tens of meters or more in the case of an urban surface. However, in the case of a shallow boundary layer (small z_i and large roughness elements), no inertial sublayer may be present at all.

Internal Boundary Layers

The above considerations are valid for horizontally homogenous surfaces. In the presence of a pronounced small-scale variability of surface properties, internal boundary layers may form downwind of each major change in the surface characteristics. Internal boundary layers may be 'thermal' if they are primarily prompted by an abrupt change in surface temperature, as for example across a shoreline. Alternatively, if changes are primarily in the surface roughness, internal boundary layers are called 'mechanical.' Most common is, of course, the development of combined thermal and mechanical internal boundary layers.

Internal boundary layers increase in depth with distance downstream from the surface discontinuities causing their development. Within a developing internal boundary layer, profiles of climate variables exhibit a continuous transition from conditions adjusted to the new surface characteristics close to the ground, to conditions still nearly in equilibrium with the conditions upstream of the leading edge. At still greater heights, horizontal gradients associated with surface heterogeneities become negligibly small due to the effects of turbulent mixing. The concept of a blending height has been introduced to denote the level at which the flow becomes independent of the local surface condition. In its strictest sense, the study of microclimate over heterogeneous surfaces is then confined to the airspace below the blending height.

Surface Characteristics

The surface characteristics that determine the microclimate can be organized according to which aspect of the

atmospheric dynamics and thermodynamics they affect for the most part:

- ‘Radiative properties’ determine the radiation budget. These are the albedo (α), or surface reflectivity in the shortwave band of the radiation spectrum; the emissivity of the effective surface (ϵ); and the geometric properties that influence the receipt and loss of radiation, such as the sky-view factor in the case of an urban surface or the canopy extinction coefficient (κ_e) in the case of a vegetated surface.
- ‘Aerodynamic properties’ determine the momentum budget. These are the surface roughness length (z_0), the zero-plane displacement (d), and the drag coefficient (C_d).
- ‘Thermal properties’ determine the heat flow in the underlying substrate–roughness elements. These are the thermal conductivity (κ_g), the heat capacity (c_g), and the thermal diffusivity ($\lambda_g = \kappa_g/c_g$). In soils, all of these properties strongly depend on the soil water content (SWC).
- ‘Soil hydraulic properties and vegetation characteristics’ affect soil moisture, the availability of water for evaporation and transpiration, and hence the partitioning between the turbulent energy fluxes and the conductive ground heat flux in the surface energy balance.
- ‘Vegetation properties’ control the distribution of radiation and the transfer of water vapor and trace gases within a canopy. In many modeling studies, these are primarily the Leaf Area Index (LAI) and stomatal conductance (γ_{st}), but they should more properly encompass all botanical, physiological, and geometric characteristics as well as species composition.
- ‘Water properties’ control the thermal state and the phase transitions in water bodies, in particular during the seasonal development of snow covers and ice bodies at high latitudes and elevated altitudes. These include, among others, the volumetric heat capacities of water (c_w) and ice (c_i), and the latent heat of fusion (L_f) and vaporization (L_v).

Although, in general, all properties concur in determining the local microclimate, their relative importance may vary

depending on the specific circumstances. Table 1 provides examples of parameters that are particularly significant in relation to specific surface types and situations. In many instances, the effective surface cannot be treated as static but undergoes dynamic changes. The examples in Table 1 emphasize the dynamic effects of the wind, either in the case of bending roughness elements (vegetated surfaces) or in the presence of water (waves) and snow (drift) surfaces.

In complex terrain, the topographic characteristics that control the development of ‘mesoscale circulation systems,’ such as land and sea breezes or mountain and valley winds, need also to be taken into account to understand the nature of microclimates.

The Budget Equations

The main role of the surface properties discussed in this article is to regulate the exchange of radiation, heat, and mass (water and carbon or other trace gases) between the ground and the atmosphere, establishing corresponding balances defined by the following budget equations:

- Radiation:

$$Q^* = K\downarrow - K\uparrow + L\downarrow - L\uparrow \quad [1]$$

- Energy:

$$Q^* = Q_E + Q_H + Q_G + \Delta Q_S \quad [2]$$

- Water (mass):

$$P = E + R + I_n + \Delta W \quad [3]$$

In these equations, Q^* denotes the net (all-wave) radiation flux at the surface; $K\downarrow$ and $K\uparrow$ are the incoming and

Table 1 Relevant microclimatological parameters for broad categories of characteristic surfaces and for selected aspects of the establishment of local microclimates

Surface type	Relevant parameters	Particular aspects
Bare soil	α , ϵ , z_0 , c_g (SWC), κ_g (SWC)	Usually considered the simplest case of surfaces, providing in many cases a reference; soil thermal properties depend on SWC, which may also affect the albedo.
Short vegetation (crops)	α , ϵ , z_0 , d , LAI, γ_{st} , κ_e	Flexible roughness elements; zero-plane displacement is relatively small and in many cases negligible; in crops there is pronounced seasonal development, with the growth stage determining the LAI and eventually the exchange of radiation, energy, and water.
Tall vegetation (forest)	α , ϵ , z_0 , d , LAI, γ_{st} , κ_e	Strong dynamic interactions with the atmospheric flow; often nonuniform vertical distribution of leaf density; importance of the storage terms in the balance equations.
Water	α , z_0 , C_d	Albedo is a function of solar elevation (diurnal variations) and momentum exchange, as controlled by z_0 or C_d ; strongly dependent on wind regime and resulting wave height (Charnock’s roughness length model).
Snow and ice	α , ϵ , z_0 , c_w , c_i , L_f , L_v	Albedo depends on snow or ice age (seasonal variability) and is a function of solar elevation (diurnal variability); especially with low snow densities, the surface roughness of snow covers depends on drift conditions; melting leads to well-defined surface temperature.
Urban	α , ϵ , z_0 , d , C_d , SVF	Stiff roughness elements; strong influence of the thermal properties of building material; geometry and distribution of roughness elements are of paramount importance for radiation, energy, and momentum exchange.

Figure 3 Energy fluxes appearing in the energy budget equation for a layer of finite thickness. Subscripts g and h refer to the ground level and the average canopy height z_h , respectively. Q_A denotes the contribution from horizontal advection to energy storage (ΔQ_s) in the volume. The latter is given by the divergence of all vertical and horizontal fluxes.

outgoing shortwave radiation fluxes, respectively; $L\downarrow$ and $L\uparrow$ are the incoming and outgoing longwave radiation fluxes, respectively; Q_E and Q_H are the turbulent fluxes of latent and sensible heat, respectively; Q_G is the conductive heat flux to the substrate; ΔQ_s is the change in heat storage associated with the divergence of horizontal or vertical energy fluxes that arise from the finite size of the volume under consideration; P is the water input through precipitation; E is the loss of water vapor through evapotranspiration; R is the surface runoff; I_n is the vertical infiltration into the ground; and ΔW is the change in water storage. Moreover, on the right-hand side of the energy and water budget equations, fluxes directed away (toward) the surface are considered positive (negative).

In the presence of snow and ice, transitions between the solid and liquid phases (melting and freezing) significantly contribute to both the energy and mass budgets. In urban environments, anthropogenic heat release also adds another contribution to the energy budget. In the case of vegetated surfaces, the net photosynthetic heat uptake or release appears as an additional term in the energy budget equation. Furthermore, in this latter case, the water budget equation needs to be modified to account for the interception of precipitation and the buildup of an interception store, from which water can evaporate.

Another important remark should be made in relation to the budget equations. Although it is customary to refer to

eqns [1]–[3] as the ‘surface balance equations,’ it is essential to recall that in most cases they are established with respect to a layer of finite thickness (Figure 3). This makes it necessary to include the storage terms that account for changes in the energy and mass content of this layer (ΔQ_s and ΔW , respectively). The storage terms become particularly important when dealing with the microclimates of vegetative canopies or urban areas.

Profiles of Mean Quantities and Turbulence Characteristics

One of the fundamental characteristics of climate variables in the atmospheric layer directly affected by the surface is their pronounced vertical variability. The associated ‘vertical profiles’ again depend in a systematic way on the surface properties, displaying temporal variations in correspondence to the time scales that characterize the governing budget equations.

Figure 4 exemplarily shows daytime profiles of mean wind speed and potential temperature above a bare soil and a forest. In the panel on the right-hand side of the figure, $d + z_0$ refers to the height above which the shapes of the profiles start to become comparable to those observed over a bare soil. This feature of the profiles implies that they can be formulated using z_0 and d as characteristic length scales. A ‘bare soil’ or relatively

Figure 4 Typical daytime mean vertical profiles of mean wind speed ($\bar{u}$) and potential temperature ($\bar{\theta}$) over a bare soil (left) and a vegetated surface (right). On the right-hand side of the figure, z_h denotes the average height of the canopy, $d \sim 2/3z_h$ is the zero-plane displacement, and $z_0 \sim 0.1z_h$ is the roughness length.

smooth surface (lower-right corner in Figure 2) would then simply be characterized through a very small zero-plane displacement.

The form of the profiles is, in general, complex. Under strongly simplifying assumptions, the profiles can nevertheless be approximated by analytical equations. Well established from theoretical and experimental studies, as well as from laboratory flow experiments, is the 'logarithmic wind profile,' or log-profile (eqn [4]). Strictly speaking, the log-profile is valid over only bare, flat, homogenous terrain and at a sufficiently large distance from the surface (i.e., within the inertial sublayer), and it can be described on the basis of the Monin–Obukhov similarity theory. For negligibly small d , it reads:

$$\bar{u}(z) = \frac{u_*}{k} \left[\ln\left(\frac{z}{z_0}\right) - \Psi_M\left(\frac{z}{L}\right) \right] \quad [4]$$

where u_* is the 'friction velocity' as determined by the Reynolds stress at z_r , $k = 0.4$ is the von Kármán constant, and the effect of atmospheric stability is taken into account through the so-called Obukhov length L and the associated stability function Ψ_M . In the case of a nonnegligible zero-plane displacement, z should be replaced by the reduced height $z - d$.

In practical applications, zero-plane displacement and roughness length can be determined from fitting observed wind speed profiles to eqn [4] or, alternatively, from morphometric properties of the surface. As a rule of thumb, $d \sim 2/3 z_h$ and $z_0 \sim 0.1 z_h$ may be used.

Within the roughness sublayer, the mean wind speed departs from the logarithmic behavior, with a strong retardation at the mean height of the roughness elements (Figure 4) due to form and viscous drag. Under special conditions, the momentum balance equation for the roughness sublayer can be solved analytically to yield an exponential function usually expressed as:

$$\bar{u}(z) = \bar{u}(z_h) \exp \left\{ -a \left(1 - \frac{z}{z_h} \right) \right\} \quad [5]$$

where a is a parameter that depends on the density and character of the roughness elements and is experimentally found to be in the range of 1–4. Note that while stability is a strong factor determining the shape of the wind profile away from the surface, the form, character, and distribution of roughness elements exert a much stronger influence within the roughness sublayer than stability does. For this reason, eqn [5] without stability extension provides a very good first-order approximation.

Variables other than wind speed and temperature also display characteristic vertical profiles. In plant stands, the vertical distribution of net radiation depends on the albedo of the canopy, as well as on the extinction of solar radiation and the absorption and emission of thermal radiation at different levels within the canopy. Owing to the greater absorption in the visible range compared to the near-infrared range, the spectral composition of the solar radiation flux varies from the top to the bottom of a stand.

Profiles of humidity and CO₂ (not shown) in forest stands often display an inflection point within the canopy, as illustrated for potential temperature in Figure 4. This feature can be explained by the divergence of the relevant energy and mass fluxes, the distribution of the sources and sinks of water vapor

and CO₂ (including those at ground level), and advective effects.

In plant stands, turbulence statistics such as velocity variances or turbulent fluxes of sensible heat and momentum exhibit a strong reduction in magnitude from the canopy top to the ground, where very small or vanishing values are observed. The most striking feature of canopy turbulence is probably the fact that it is governed by so-called coherent structures with spatial scales on the order of the canopy height. As a consequence, the turbulent exchange of heat, moisture, or trace gases within canopies is often characterized by countergradient transport. This means that 'K theory,' which is based on the assumption of small dominating eddies and is a well-established concept for the inertial sublayer, is not a useful description of turbulent transport in the roughness sublayer.

Owing to the rough nature of the surface, turbulent mixing is stronger in the upper part of the roughness sublayer than in the inertial sublayer. As for the fluxes of sensible and latent heat, this increase is most pronounced under near-neutral conditions. In this case, the turbulent transport just above the canopy can be up to three times larger than in the inertial sublayer, whereas for momentum the enhancement is of the order of 10%.

Comparison of Urban and Rural Microclimates

The ways in which microclimates are shaped by properties of the underlying surfaces can be illustrated by contrasting rural and urban environments. Radiative energy fluxes over the urban surface are different from those found in rural areas, mainly due to enhanced aerosol load and smaller albedo in the urban environment. The latter reflects the fact that a substantial part of the shortwave incoming radiation is trapped between the buildings, heating up the surface material. During the daytime hours (Figure 5(a)), the urban environment gets more net radiative energy due to the smaller albedo. During night, on the other hand, the net radiation is typically larger over a rural than over an urban surface (Figure 5(b)) owing to differences in the longwave loss.

Spatial heterogeneity in the availability of water for evapotranspiration in an urban fabric typically leads to a substantially different partitioning of the atmospheric energy fluxes across different surface types, which is best illustrated in terms of the Bowen ratio, that is, the ratio of sensible to latent heat, $\beta = Q_H/Q_E$ (Figure 6). For this particular case (a midlatitude European type of city structure), the turbulent flux of sensible heat (Q_H) dominates the latent heat flux (Q_E) over the urban surface ($\beta \approx 2$), while the situation is reversed ($\beta \approx 0.5$) over the nearby rural surfaces, with the suburban sites exhibiting an intermediate behavior. For all types of surfaces, the partitioning of the available energy between latent and sensible heat undergoes a pronounced daily cycle, reflecting changes in the vertical profiles of wind speed, temperature, humidity, and, in the case of the urban environment, heat storage (ΔQ_s).

The characteristic energy flux partitioning seen in Figure 6 results in an enhanced near-surface temperature within an urban area that usually is referred to as the 'urban heat island'

Figure 5 (a) Average daily cycles of the radiation balance components at an urban site in the city of Basel, Switzerland (data from September 2001 to August 2002); (b) daily cycle of the corresponding urban–rural difference (ΔQ_{U-R}) for these mean radiation fluxes ('urban' data are averaged over two urban sites, and 'rural' data are averaged over three rural sites around Basel); and (c) daily cycle of urban–rural difference in temperature (gray lines, left scale) and absolute humidity (black line, right scale). Note that ΔT_{U-R} represents a measure of the so-called urban heat island (see text for details); the data represent averages from two sites (urban) and three sites (rural), respectively, and stem from one summer month of the full-year data of (a) and (b). Composed from figures in Christen, A., 2005. *Atmospheric Turbulence and Surface Exchange in Urban Environments*, PhD dissertation, University of Basel, Switzerland, published as *stratus* 11, p. 140.

(UHI). The UHI is often associated with a drier urban environment, and its strength is a strong function of time and position within the roughness sublayer (Figure 5(c)).

Apart from being related to the size of the urban population (i.e., the city), the maximum strength of the UHI has been shown in other studies to be associated with geometric and surface properties of the urban environment (Figure 7).

Within and above urban canopy layers, temperature, humidity, and wind speed exhibit characteristic profiles similar to those shown in Figure 4 (right) for a forest stand. These profiles are the result of turbulent exchange processes, which are strongly determined by the character of the roughness elements (form and building material) and their density and

height distribution. Far away from the roughness elements (i.e., within the inertial sublayer), these turbulent fluxes are essentially constant with height, and this corresponds to the situation over relatively smooth surfaces. Closer to the surface, however, the complicated distribution of sources and sinks yields more complicated profiles (Figure 8). The distribution of sources and sinks of heat and air pollutants, from traffic at the street level and chimneys from domestic heating near rooftops, suggests that in urban environments, profiles of the sensible heat flux, mean temperature, and air pollutants are less systematic than corresponding profiles of the momentum flux, for which the main sink is at ground level. Vertical variations in turbulent fluxes also affect the height distribution of other turbulence-related variables such as velocity or scalar variances. These, in turn, govern the turbulent diffusion of energy, water vapor, and air pollutants.

Figure 8 Mean profiles of turbulent fluxes of momentum $\langle u'w' \rangle$ (left) and sensible heat $\langle w'\theta' \rangle$ (right), normalized with their respective values far from the roughness elements. In the case of the momentum flux, normalization was achieved with the square of the friction velocity to preserve the negative sign. The two gray areas indicate the height range where pronounced inflection points appear in the profiles. For both fluxes, the dashed and dotted lines represent profiles taken within the urban area, whereas the thick continuous lines refer to profiles collected in a suburban environment. Modeling and Parameterization

Synopsis

In this contribution we deal with the representation of the atmospheric boundary layer (ABL) for modeling studies of weather, climate, and air quality. As such we review the major characteristics of the ABL, and summarize the basic parameterizations for the description of atmospheric turbulence and the surface fluxes, where we emphasize the modeling and parameterization of turbulence in the atmospheric boundary layer over land without clouds. The modeling principles are illustrated with the outcome of single-column and mesoscale models for a variety of conditions using field data and fine-scale model results. For readers not familiar with atmospheric turbulence and meteorology, some background and basic definitions are also given.

Introduction

The atmospheric boundary layer (ABL) is the lower part of the atmosphere which is in continuous interaction with the earth's surface due to friction and heating or cooling (Stull, 1988; Garratt, 1992). The ABL is therefore generally characterized by turbulence and a diurnal cycle of temperature, wind, specific humidity, and other tracers in particular over land. Because of its capability to mix air with different properties efficiently, the representation of turbulence is directly relevant for atmospheric and environmental modeling. For instance, turbulence directly impacts on the transfer of momentum, sensible heat, water vapor, ozone, and methane, among many other quantities, between the earth's surface and the atmosphere. Turbulence also defines the mixing of properties inside the atmospheric boundary layer, the transfer of quantities between the boundary layer and the clear or cloudy atmosphere aloft, and the mixing inside clouds.

Turbulence in the atmospheric boundary layer is the three-dimensional, chaotic flow of air with timescales typically between a second and an hour (e.g., Tennekes and Lumley, 1982). The corresponding length scales are from a millimeter up to the depth of the boundary layer (or more in the case of clouds). The depth of the dry ABL can vary over land between tens of meters during night up to kilometers during daytime (Figure 1). Over sea the depth is typically a few hundred meters and rather constant on the timescale of a day. Most of the atmosphere above the ABL is not turbulent, although turbulence can occur throughout the whole atmosphere. For instance, cumulus-type clouds, which may grow into thunderstorms, are always turbulent through convection produced by the heat released due to the condensation of water vapor. Turbulence can also occur in clear air above the ABL; most of this is produced in layers of strong vertical wind shear at the boundary between air masses (so-called 'clear-air turbulence').

Because of the mixing capacity of turbulence, modeling atmospheric boundary layers is relevant for many practical applications. For instance, chimney plumes are diluted and spread over larger volumes than they would be without turbulence. As such, strong local peaks of pollution are prevented and otherwise clean air is polluted (e.g., Nieuwstadt and van Dop, 1982). In practice turbulence may also cause

engineering problems, because it shakes structures such as bridges, towers, and airplanes, causing failure of such systems in extreme cases. Turbulent fluctuations in the horizontal motions during severe storms can be fatal to tall buildings or bridges, particularly if resonance (e.g., forcing of a system at its natural frequency) occurs.

The correct formulation of the overall effects by turbulence, either inside or outside the atmospheric boundary layer, is an essential part of atmospheric models dealing with the prediction and study of weather, climate, and air quality. These models are based on solving the equations dealing with atmospheric behavior. Even with state-of-the-art computers, the number of grid points in atmospheric models is limited. This implies that on the regional and global scale the atmospheric model equations are usually applied to fairly large 'air boxes.' Such boxes are in the order of 10–100 km wide and ten to a few hundred meters thick. In these large boxes, small-scale motions make air parcels interact and mix. For example, if a hot parcel is located next to a cold parcel, turbulent motion at their boundaries will heat the cool and cool the hot parcel. Thus, a closure formulation is needed to reproduce mixing by the turbulent motions into the model-resolved scales using the equations for the large-scale 'mean' motions. It is important to realize that the closure formulation needs to be expressed in terms of variables available

Figure 1 Idealized diurnal evolution of the atmospheric boundary layer over land in fair weather. After Stull, R.B., 1988. *An Introduction to Boundary-Layer Meteorology*. Kluwer Academic Publishers, Dordrecht, 666 pp. (reprinted 1999).

in the modeling context. This is called a 'parameterization' (Stull, 1988; Garratt, 1992; Pielke, 2001).

Background

Atmospheric models for the forecasting and study of weather, climate, and air quality are typically based on integration of the basic equations governing atmospheric behavior. These equations are the gas law, the equation of continuity (mass), the first law of thermodynamics (heat), the conservation equations for momentum (the so-called 'Navier–Stokes equations'), and usually equations expressing the conservation of moisture, trace gases, and air pollutants. At one extreme, atmospheric models may deal with the world's climate and climate change; at the other, they may account for the behavior of local flows at coasts, in mountain-valley areas, or even deal with individual clouds. This all depends on the selected horizontal modeling domain and the available computing resources.

Since there is an enormous range of scales in atmospheric motion and turbulence, there is a need to separate the scales of atmospheric turbulence from large-scale motions. Let C denote an atmospheric variable, such as specific humidity. Then $\bar{C}$ represents a mean or 'smoothed' value of C , typically taken on a horizontal scale of order 10 (or more) km and a corresponding timescale in the order of 10 min–1 h. A local or instantaneous value of C would differ from $\bar{C}$. Thus, we have

$$C = \bar{C} + c. \quad [1]$$

Here c represents the small-scale fluctuations. Note that we use lower case for the latter (often primes are used as well to indicate fluctuations). In principle, the fluctuations around the mean motion also reflect gravity waves and other small-scale motions, in addition to turbulence. Gravity waves often coexist with turbulence or are generated by turbulence. If the wind at the same time is weak, there may be no turbulence at all. Anyhow, if turbulence exists, it is usually more important for most atmospheric applications, because it mixes more efficiently than the other small-scale motions.

To make the mathematical handling of c tractable, it must satisfy the so-called 'Reynolds postulates.' These require, for example, that $\bar{c} = 0$ and that small- and large-scale values must not be correlated. After a quantity has been averaged to create a large-scale quantity, further averaging should produce no further changes, in order for this postulate to apply. The mean of the summation of two variables A and C will produce $\overline{A \pm C} = \bar{A} \pm \bar{C}$. A further condition is that a mean variable $\bar{C}$ must be differentiable, since differentials show up in the atmospheric equations (see below). In practice, not all these conditions are rigorously satisfied. If the Reynolds postulates are fulfilled, then the averaging for the product of two variables provides

$$\overline{AC} = \bar{A}\bar{C} + \overline{ac}. \quad [2]$$

The second term at the right hand side of eqn [2] is known as the turbulent covariance. Similarly, the turbulence variance of a quantity is given by $\overline{C^2} - (\bar{C})^2$ (which is the square of the standard deviation).

If in eqn [2], the variable represents one of the velocity components (U, V, W in the x, y, z direction, respectively), then

$\overline{AC}$ is the total flux of C and the second term at the right hand side of eqn [2] represents a turbulent flux of C . For instance, $\overline{uc}$ and $\overline{wc}$ are the horizontal and vertical turbulent fluxes of the variable C , respectively. Here u and w are the turbulent fluctuations of the horizontal and vertical velocities. Near the surface, the mean vertical wind $\bar{W}$ is usually small, and thus the total vertical fluxes are normally dominated by the turbulent contributions.

Atmospheric Boundary-Layer Structure

Turbulent fluctuations, variances, and fluxes of variables are influenced by the vertical boundary-layer structure. Here the variation of temperature in the atmospheric boundary layer plays an important role. Since pressure decreases with altitude, air parcels, which are forced to rise (sink), do expand (compress). According to the first law of thermodynamics, a rising (sinking) parcel will cool (warm) if there is no additional energy source such as condensation of water vapor. Then this is called a dry adiabatic process.

It can be shown that in the atmospheric boundary layer, the temperature (T) variation with height for a dry adiabatic process is $dT/dz = -g/C_p$ (here g is gravity constant and C_p is specific heat at constant pressure). The value for g/C_p is approximately 1 K per 100 m. An atmospheric layer which has such a temperature variation with height is called neutral for dry air (at least when there is no convection arising from other levels). In that case $\Theta = T + (g/C_p)z$ is constant, where Θ is called the potential temperature (note that the previous definition for potential temperature is not accurate above the boundary layer). Since air normally contains water vapor and because moist air is lighter than dry air, we have to correct for the influence of this on vertical motions. Consequently, a virtual potential temperature is defined as $\Theta_v = \Theta(1 + 0.61q)$, where q is the specific humidity (defined as the mass of water vapor per unit mass of moist air).

In a neutral layer with constant Θ_v , vertical motions of moist (not saturated) air can maintain themselves. If the virtual potential temperature of the atmospheric layer increases with height, vertical displacements are suppressed. This is called a stable condition (or 'inversion'). At the other hand, when the virtual potential temperature decreases with height, vertical fluctuations may be accelerated. Consequently this is called an unstable condition. Thus in considerations with turbulent fluctuations and atmospheric stability, we have to deal with the virtual potential temperature and not with the actual temperature. Similarly, the vertical flux of sensible heat is connected to turbulent fluctuations of (virtual) potential temperature; e.g., it reads as $\overline{w\theta_v}$ (in m K s^{-1}). The latter relates directly to the energy per time and unit area H by $H = \rho C_p \overline{w\theta_v}$ (in W m^{-2}), where ρ is density of the air (in kg m^{-3}).

Figure 2 (after Stull, 1988) provides the typical, idealized, mean vertical profiles for temperature T , potential temperature Θ , specific humidity q , in addition to the horizontal wind M (defined by $M^2 = U^2 + V^2$). These profiles apply for an atmospheric boundary layer over land in clear sky conditions in the afternoon and around midnight. Note that in the free atmosphere the horizontal wind is mostly a result of the acting of the large-scale pressure differences and the Coriolis force due

Figure 2 Idealized vertical profiles of mean variables in the atmospheric boundary layer over land in fair weather. See text for additional information. After Stull, R.B., 1988. *An Introduction to Boundary-Layer Meteorology*. Kluwer Academic Publishers, Dordrecht, 666 pp. (reprinted 1999).

to the rotation of the earth (but other effects may play a role as well). The resulting wind is known as the ‘geostrophic’ wind and indicated with G in **Figure 2** (see dashed line). In the daytime boundary layer the actual wind is smaller due to surface friction, while at clear nights the actual wind away from the surface may be substantially stronger than G due to inertial effects (resulting in the so-called ‘low-level jet’).

The temporal variation of the mean boundary-layer profiles over land can be quite substantial due to the strong diurnal variation of solar incoming radiation and the nighttime cooling at the land surface. During daytime the turbulent boundary layer may grow to several kilometers into the nonturbulent ‘free atmosphere’ (indicated as FA in **Figure 2**). At night the turbulent part of the stable boundary layer (SBL) may only extend up to a few hundred meters or less (the lowest dashed line in the lower figure). An idealized picture for the temporal variation of the boundary layer over land is given in **Figure 1** (after Stull, 1988). Here the arrows with local time indications refer to the day and nighttime figures of **Figure 2**.

Figure 2 also indicates that the boundary layer during daytime shows a three-layer structure: an unstable ‘surface layer,’ a ‘well-mixed layer’ with rather uniform (virtual) potential temperature, and a stably stratified ‘entrainment zone.’ In the latter zone, turbulence acts to exchange heat, momentum, water vapor, and trace gases between the boundary layer and the free

atmosphere. During nighttime, often the vertical structure of the previous day persists above the SBL. As such a ‘residual layer’ with sporadic turbulence (remaining from the previous day) can be identified as well as a ‘capping inversion.’

Modeling

The challenge of modeling the atmospheric boundary layer is the prediction of the temporal variation of the vertical and horizontal structures in response to the influence of the major processes acting in the atmosphere and at the earth’s surface. As such the governing equations have to be integrated. In practice, the variables are split into ‘mean’ large-scale motions and small-scale fluctuations as in [eqn \[1\]](#). Inserting this into the basic equations and after averaging this provides a set of equations for the behavior of the large-scale (mean) variables. The large-scale variables are then used explicitly in atmospheric models. This can be demonstrated as follows (Stull, 1988; Garratt, 1992; Pielke, 2001; Holtslag and Duynkerke, 1998).

The general character of any of the budget equations dealing with atmospheric motions is

$$\frac{dC}{dt} = S_i. \quad [3a]$$

Here S_i represents the subsequent sources and sinks for the variable C (such as radiation or chemistry effects). The notation dC/dt represents the total rate of change for the variable C by local changes ($\partial/\partial t$), and changes transported with the fluid motion in the three directions. As such, we have

$$\frac{\partial C}{\partial t} + U \frac{\partial C}{\partial x} + V \frac{\partial C}{\partial y} + W \frac{\partial C}{\partial z} = S_i. \quad [3b]$$

Here U , V , W are the wind speeds in the three directions x , y , z , respectively.

If in the atmospheric motion each variable is split into a mean component and a fluctuation then eqn [3b] provides after Reynolds-averaging, some algebraic manipulations and simplifying assumptions, a budget equation for the mean variable $\bar{C}$. This reads as

$$\frac{d\bar{C}}{dt} = \frac{\partial \bar{C}}{\partial t} + \bar{U} \frac{\partial \bar{C}}{\partial x} + \bar{V} \frac{\partial \bar{C}}{\partial y} + \bar{W} \frac{\partial \bar{C}}{\partial z} = \bar{S}_i - \frac{\partial \bar{u}\bar{c}}{\partial x} - \frac{\partial \bar{v}\bar{c}}{\partial y} - \frac{\partial \bar{w}\bar{c}}{\partial z}. \quad [4]$$

We may note that in the derivation of eqn [4], single terms representing fluctuations have disappeared (as above in eqn [2]). However, terms involving the product of two fluctuations did remain.

Thus because the basic equations are nonlinear, the budget equations for the mean variables contain terms involving small-scale motions. The latter terms are of the form of a divergence of fluxes produced by such motions in the three directions and appear as the last three terms in eqn [4]. These motions are said to be subgrid and consequently, closure formulations or parameterizations are needed to introduce mixing by the small-scale, subgrid motions into the equations for the large-scale motions (as resolved by the model). Note that additional terms may also appear in eqn [4] when the source or sink term S_i incorporates nonlinear effects (such as in the case of chemistry).

A special and simple form of eqn [4] arises for horizontally homogeneous conditions. In such cases the terms including horizontal derivatives are negligible. If in addition the mean vertical wind is small and if there are no other sources and sinks, then eqn [4] provides

$$\frac{\partial \bar{C}}{\partial t} = - \frac{\partial \bar{w}\bar{c}}{\partial z}. \quad [5]$$

This equation is known as the one-dimensional, vertical diffusion equation. It shows that the local time rate of change for the mean of a variable (such as temperature or wind) at a certain height is given by the divergence of the turbulent (corresponding heat or momentum) flux in the vertical direction. As such, information on the turbulent flux may produce a local forecast of the variation of a mean variable (but only under the simplifications mentioned). However, normally the other terms in eqn [4] are also relevant, in particular the terms with mean wind speed (the so-called 'advection terms'). This means that in general the budget equations for momentum, heat, and the various scalars are closely coupled in any atmospheric model.

Equation [4] can also be integrated in the vertical direction to account for the averaged effect of turbulence on the boundary layer development. This is particularly suitable for very unstable boundary layers, which are more or less uniformly mixed by the dominant presence of convection. A well-mixed structure is frequently observed for potential

temperature in daytime convective conditions over land (Figure 2). Integration of eqn [4] provides (e.g., Garratt, 1992)

$$h \frac{d\langle \bar{C} \rangle}{dt} = \bar{w}\bar{c}_0 - \bar{w}\bar{c}_e. \quad [6]$$

Note that we have neglected the horizontal fluxes and the source term S_i here for simplicity. In eqn [6], $\langle \bar{C} \rangle$ is the mean concentration across the boundary layer, h is the mean depth of the turbulent boundary layer, $\bar{w}\bar{c}_0$ is the surface flux, and $\bar{w}\bar{c}_e$ is the flux at the top of the boundary layer. The latter represents the exchange of C through entrainment of air from above the boundary layer into the ABL.

Equation [6] can be used to solve for the time development of $\langle \bar{C} \rangle$, but a separate equation for the boundary layer depth is needed in addition to information on the fluxes at the top and bottom of the ABL. Such an approach is known as 'bulk' or 'mixed-layer' modeling. For clear boundary layers, it appears that the entrainment flux for heat at the top of the boundary layer is proportional to the surface heat flux and to surface friction. However, for cloudy boundary layers the parameterization of the entrainment flux is not that simple.

Before we proceed with more detailed parameterizations for the fluxes in the boundary layer, let us deal with the derivation of the surface fluxes. These fluxes enter as boundary conditions when solving the budget equations for all the relevant mean variables (in any approach). It is important to realize that near the surface, the average wind must vanish because the mean wind is zero at the earth's surface. At the other hand, we know from observations that the fluxes of heat, momentum, and trace gases are nonzero. Consequently, it is convenient to model an 'effective' surface flux $\bar{w}\bar{c}_0$ of a conserved variable due to the combined effect of molecular diffusion and turbulence at the surface. This can be achieved by writing (e.g., Beljaars and Holtslag, 1991)

$$\bar{w}\bar{c}_0 = \beta_t w_t (C_0 - C_a). \quad [7]$$

Here, C_0 and C_a are the values of the transported variable at the surface and in the air, respectively; β_t is a transfer coefficient, and w_t is an effective transport velocity representing the turbulence. For example, in near-neutral conditions the effective transport velocity is well represented by the so-called surface friction velocity u_{*0} (which is related to the surface momentum flux). Then it can be shown that $\beta_t = \kappa / \ln(z/z_0)$, where κ is the 'Von Karman' constant (often specified as $\kappa \cong 0.4$), z is the corresponding height of C_a in the lowest part of the boundary layer, and z_0 is the so-called surface roughness length for the variable C .

Diagnostic Local Mixing Parameterizations

To solve the budget eqn [4] for all the mean atmospheric variables involved, the terms involving turbulent fluxes need to be parameterized. As mentioned before, this means that the fluxes need to be expressed in terms of available mean model quantities, both in the atmosphere and at the surface. Once this has been achieved, the atmospheric model equations can be integrated. Thus, starting with proper initial values, new values can be calculated for the following time step and so on.

The most frequently used parameterization for environmental and atmospheric models is known as first-order closure

or often also called K -theory. In this theory it is assumed that the flux $\overline{wC}$ of a variable C in the vertical direction z is down the vertical gradient of the mean concentration of C per unit mass. Thus

$$\overline{wC} = -K_c \frac{\partial \overline{C}}{\partial z}. \quad [8]$$

Here, K_c is known as the 'eddy-diffusivity' or mixing coefficient for the variable C . Similarly, the horizontal fluxes can be represented in terms of horizontal gradients. Note that the corresponding eddy-diffusivities are typically not constant, but that they generally depend on properties of the flow and the variable of interest. This also means that normally no analytic solutions are possible, not even for the simple case in which eqns [5] and [8] are combined.

We may note that the dimension of an eddy-diffusivity is a length scale l times a velocity scale. These are proportional to the products of effective eddy sizes and eddy velocities in the corresponding directions. Often a diagnostic expression is used for the eddy-diffusivity, on basis of what is called 'mixing length theory' (in analogy with molecular diffusion). The result reads as

$$K_c = l^2 S f(Ri). \quad [9]$$

Here S is vertical wind shear (that is the variation of mean horizontal wind with height). Note that the combination lS in eqn [9] has units of velocity. In eqn [9], $f(Ri)$ denotes a functional dependence on local stability as represented by the gradient Richardson-number Ri defined by

$$Ri = \frac{g}{\Theta_v} \frac{\partial \overline{\Theta_v} / \partial z}{(\partial \overline{U} / \partial z)^2 + (\partial \overline{V} / \partial z)^2}. \quad [10]$$

Here g is the acceleration due to gravity and $\overline{\Theta_v}$ is the mean 'virtual potential temperature.'

The specification of the length scale l is not at all straightforward, except near the surface where the so-called 'surface-layer similarity theory' (Stull, 1988) provides that $l \propto z$. A frequently used form for l is

$$\frac{1}{l} = \frac{1}{\kappa z} + \frac{1}{\lambda}. \quad [11]$$

Here λ is a turbulent length scale, which should be valid for the turbulence far above the surface. We note that the latter has a rather empirical nature and consequently there is no agreement on the specification of λ in the literature.

Equations [9] and [11] are diagnostic equations, which indicate that the eddy-diffusivity varies with height, wind speed, stability, etc. In combination with the flux parameterization of eqn [8], it follows that the flux at a certain height depends on the local gradient of the mean variable involved. Consequently, the approach is referred to as a 'diagnostic local mixing approach.' Such an approach is mostly suitable for relatively homogeneous conditions with neutral and stable stratification, and is not so suitable for cases with convection (see Section Nonlocal Mixing Parameterizations).

Prognostic Mixing Parameterizations

A physically realistic alternative to the diagnostic approach is to relate the eddy-diffusivity of eqn [8] to the actual turbulent

kinetic energy of the flow, by using the prognostic turbulent kinetic energy (TKE) equation and an appropriate choice for the turbulent length scale. It is important to realize that the kinetic energy of atmospheric motion per unit of mass E is given by half of the sum of the velocities squared in the three directions (as in classic mechanics), e.g., $E = (U^2 + V^2 + W^2)/2$. Similar as with respect to eqn [2], we can separate between the mean kinetic energy $\overline{E}$ of the mean atmospheric motions and the Turbulent Kinetic Energy (TKE or e) of the small-scale fluctuating motions by turbulence. Thus e is given by $e = (\overline{u^2} + \overline{v^2} + \overline{w^2})/2$.

The prognostic equation for e reads in its basic form as

$$\frac{de}{dt} = -\overline{uw} \frac{\partial \overline{U}}{\partial z} - \overline{vw} \frac{\partial \overline{V}}{\partial z} + \frac{g}{\Theta_v} \overline{w\theta_v} + D - \varepsilon. \quad [12]$$

Here de/dt is the total variation of e with time (the sum of local variations and those transported with the mean air motion). The two terms at the immediate right hand side of eqn [12] represent the shear production of turbulence. These depend primarily on vertical variations of wind or, near the ground, on wind speed and surface roughness. The terms are almost always positive. The third term in eqn [12] represents the rate of production or breakdown of turbulence by buoyancy effects (such as heat convection). It depends directly on density effects, which can be written in terms of the virtual potential temperature $\overline{\Theta_v}$, and its turbulent flux $\overline{w\theta_v}$. The term D in eqn [12] represents divergence and pressure redistribution terms. These have a tendency to cancel near the surface. Finally, the term ε reflects the molecular dissipation of turbulence into heat and this term is always positive. In fact ε is typically proportional to e/τ , where τ is the characteristic timescale for the turbulent mixing process.

Using eqn [12], TKE can be calculated for given mean profiles when the corresponding fluxes are calculated using eqn [8] for all fluxes involved. In this approach the diffusivities are typically calculated with equations of the form

$$K_c = \alpha_c l \sqrt{e}. \quad [13]$$

Here α_c is a constant depending on the variable of interest. The length scale is typically calculated with a similar type of diagnostic equation as given by eqn [11]. This approach is known as the 'TKE-length scale approach' and it is an example of the so-called 1.5-order closure. Sometimes a prognostic equation is used for the length scale as well, but such an approach is more popular in engineering applications and then in the atmospheric sciences.

It can be shown that eqn [9] is a solution of eqns [12] and [13] in stationary conditions and when other simplifications are made such as the neglect of the influences by advection and turbulence divergence in the TKE equation. A more advanced turbulence scheme is known as 'second-order closure.' In such an approach, prognostic equations are developed for the fluxes and variances themselves. Such equations have a very similar structure as eqn [12] for kinetic energy. Unfortunately, new unknowns are present in these equations. These must be related to the other variables in the model equations, always involving assumptions. Thus, second-order closure involves many more than the original equations and is therefore computationally more time-consuming ('expensive') than first-order and 1.5-order closure.

One may expect that a model with 1.5- or second-order closure would produce more realistic results than a model with a first-order closure. However, in practice this is often not the case, because of complex model interactions and the difficulty of representing all the relevant details with sufficient accuracy (e.g., Steeneveld et al., 2006a,b). That is the reason why diagnostic approaches remain popular. Nevertheless, second-order equations are useful to gain insight in the governing physics, and after simplification useful extensions of the basic parameterizations may be achieved.

The atmospheric model equations can also be applied on much smaller spatial and temporal scales than discussed here, for instance by using vertical and horizontal grid elements of a few to typically 100 m, and time steps of seconds only. It is important to realize that in such cases a significant part of the turbulent fluctuations are resolved by the model equations. This type of modeling is known as 'large-eddy simulation (LES)'. This has become a powerful and popular tool in the last decade to study turbulence in clear and cloudy boundary layers under well-defined conditions. It is important to realize that in the case of LES the simplifying assumptions leading to eqn [2] are normally not valid.

Model Intercomparison for Stable Conditions

As noted above, atmospheric models need to make an overall representation of the small-scale boundary layer and near surface processes. This appears to be more successful during daytime (e.g., Ek and Holtslag, 2004; Holtslag and Ek, 2005; Steeneveld et al., 2011) then during nighttime stable conditions over land (Vogelezang and Holtslag, 1996; Steeneveld et al., 2011; Svensson et al., 2011). The modeling of the SBL over land is rather complex because of the many different physical processes which are 'at work' in stable conditions (e.g., Mahrt, 1999). These small-scale processes are clear air radiation divergence, drainage flow, generation of gravity waves and shear instabilities, fog and dew formation, the occurrence of a low-level jet, and generation of discontinuous or intermittent turbulence (Van de Wiel et al., 2003, 2007). In addition, the phenomenology of stable atmospheric boundary layers is quite diverse, e.g., shallow and deep boundary layers with continuous turbulence through most of their depth, and on the other hand boundary layers with intermittent turbulence or even laminar flow.

The small-scale processes influence the vertical and horizontal exchange of quantities between the surface and the atmosphere (Holtslag et al., 2007), as well as the mixing in the atmosphere on a variety of scales. In addition, it is known that turbulent mixing in stratified flow has an inherent nonlinear character and may, as such, trigger positive feedbacks. These positive feedbacks, in turn, may cause unexpected transitions between totally different SBL regimes (e.g., Van de Wiel et al., 2003).

Having in mind the complexity, one should not be surprised that atmospheric models encounter large forecast errors for stable conditions. One strategy to improve model performance is to provide different models the same forecasting task and analyze which model descriptions are in favor for which atmospheric stability. Recently, such an

intercomparison of boundary-layer schemes for stable conditions was made within the GEWEX Atmospheric Boundary Layer Study. This GEWEX project aims to improve the understanding and the representation of the atmospheric boundary layer in regional and large-scale climate models (Holtslag, 2006; Holtslag et al., 2013). A rather simple case was selected as a benchmark to review the state of the art and to compare the skills of single column (1D) models (Cuxart et al., 2006) and large-eddy simulation models (Beare et al., 2006). In this case an SBL is driven by an imposed, uniform geostrophic wind, with a specified constant surface-cooling rate over (homogeneous) ice. The case is initialized with $\theta = 265$ K for $0 < z < 100$ and a lapse rate of 1 K per 100 m aloft.

It turns out that with the same initial conditions and model forcings, the models indicate a large range of results for the mean temperature and wind profiles. Figure 3 shows the mean profiles for several models after 9 h of constant surface cooling (sufficient to achieve a quasi-steady state). The variable results achieved are strongly related to the details of the boundary-layer mixing schemes (Cuxart et al., 2006). An important finding is that the models in use at operational weather forecast and climate centers (as depicted at the left hand side of Figure 3) typically allow for enhanced mixing resulting in too deep boundary layers, while the typical research models (at the right hand sides) show less mixing in more in agreement with the 'large-eddy simulation' results for this case (Beare et al., 2006).

Because of the enhanced mixing in weather and climate models, these models tend to show a too strong surface drag, too deep boundary layers, and an underestimation of the wind turning in the lower atmosphere (e.g., Svensson and Holtslag, 2009). At the other hand, by decreasing the mixing and surface drag, a direct impact on the atmospheric dynamics ('Ekman pumping') is noted (e.g., Beljaars and Viterbo, 1998). Consequently, cyclones may become too active, corresponding in too high extremes for wind and precipitation, etc.

Nonlocal Mixing Parameterizations

In the previous sections, we have dealt with the most popular turbulence parameterizations in use for modeling atmospheric boundary layers for weather, climate, and air quality. In the literature many more examples can be found of parameterization schemes and of comparison studies like the one of Figure 3. Here we continue our discussion with mixing parameterizations, which have been proposed for boundary layers with atmospheric convection. In such cases, the turbulent flux of a conserved quantity is typically not proportional to the local gradient alone as predicted by eqn [8]. In fact, in a large part of the ABL the mean gradients are small in conditions with dry convection, in particular for potential temperature (Figure 2). Then the fluxes depend mostly on the mixing characteristics of the large eddies across the ABL.

Theories are available, which have modified K -theory to allow for the influence of convection, for example, by including additional terms at the right hand side of eqn [8]. This reads as (e.g., Holtslag and Boville, 1993; Cuijpers and Holtslag, 1998)

$$\overline{w\epsilon} = -K_c \frac{\partial \overline{C}}{\partial z} + \overline{w\epsilon}_{nl}. \quad [14]$$

Figure 3 Modeled potential temperature and wind profiles by various single-column models (after 9 h of prescribed surface cooling starting all with the same initial profiles). Gray areas indicate the ensemble of large-eddy simulation results (Beare, R., MacVean, M., Holtslag, A., Cuxart, J., Esau, I., Golaz, J.-C., Jimenez, M., Khairoutdinov, M., Kosovic, B., Lewellen, D., Lund, T., Lundquist, J., McCabe, A., Moene, A., Noh, Y., Raasch, S., Sullivan, P., 2006. An intercomparison of large-eddy simulations of the stable boundary layer. *Boundary-Layer Meteorol.* 118, 247–272.). Left panel shows the results for operational (first-order closure) models and the right panel for research (higher-order closure) models. After Cuxart, J., Holtslag, A.A.M., Beare, R.J., Bazile, E., Beljaars, A., Cheng, A., Conangla, L., Ek, M., Freedman, F., Hamdi, R., Kerstein, A., Kitagawa, H., Lenderink, G., Lewellen, D., Mailhot, J., Mauritsen, T., Perov, V., Schayes, G., Steeneveld, G.J., Svensson, G., Taylor, P., Weng, W., Wunsch, S., Xu, K.-M., 2006. Single-column model intercomparison for a stably stratified atmospheric boundary layer. *Boundary-Layer Meteorol.* 118, 273–303.

Here $\overline{w\epsilon_{nl}}$ is the nonlocal flux representing the influence of the large-eddy mixing in the boundary layer with convection. The formulation of the latter is not so straightforward in the general case. The eddy-diffusivity K_c in eqn [14] is suitably modeled with the 1.5-order approach using the full kinetic energy equation, and a length-scale formulation, which may depend on the actual height and the depth h of the boundary layer.

In the case of a clear, stationary boundary layer dominated by dry convection, it appears that the eddy-diffusivity is also well described by a profile function (Holtslag and Moeng, 1991)

$$K_c = w_* h \left(\frac{z}{h} \right)^{4/3} \left(1 - \frac{z}{h} \right)^2, \quad [15]$$

where w_* is known as the convective velocity scale for the clear boundary layer. The latter is defined as

$$w_* = \left(\frac{g}{\Theta_v} \overline{w\theta_{v0}} h \right)^{1/3}, \quad [16]$$

where $\overline{w\theta_{v0}}$ is the surface sensible heat flux heating the boundary layer from below. For dry convection, the nonlocal flux correction term of eqn [14] is typically proportional to the surface flux of the variable involved. Then

$$\overline{w\epsilon_{nl}} = f(z/h) \overline{w\epsilon_0}, \quad [17]$$

where $f(z/h)$ is a dimensionless function of relative height. As an example, Figure 4 gives the results of two slightly different

Figure 4 A comparison of observations made in the Netherlands on 12 June 2006 at the Cabauw tower (crosses) and by radio soundings in De Bilt (open circles) with two mesoscale model results each with two versions of a nonlocal boundary layer scheme (various colored lines) for temperature (a), specific humidity (b), wind magnitude (c), and wind direction (d). Results are taken from Steeneveld, G.J., Tol, L., Moene, A.F., Hartogensis, O.K., Peters, W., Holtslag, A.A.M., 2011. Confronting the WRF and RAMS mesoscale models with innovative observations in the Netherlands—evaluating the boundary-layer heat budget. *J. Geophys. Research. D Atmos.* 116, 16.

implementations of boundary layer schemes based on similar equations as eqns [15] and [17] within two atmospheric models in comparison with observations in the Netherlands (after Steeneveld et al., 2011).

Other nonlocal flux parameterizations are also discussed in the literature such as mass flux approaches. In a mass flux approach the turbulent layer is divided into updrafts and downdrafts, each with a typical concentration for the variable of interest. The updrafts and downdrafts can be defined on basis of the sign of vertical velocity or more restrictive definitions (in the case of clouds). Using such an approach, the updraft and downdraft variables are connected to a number of equations, which can be closed when the horizontal exchange ('lateral entrainment') of mass and other variables between the up and downdrafts is treated well (Siebesma and Holtslag, 1996; Neggers et al., 2004; Siebesma et al., 2007). It is noted that the mass flux approach has been quite successful for representing cumulus and stratocumulus in atmospheric models (Emanuel, 1994).

Summary

In this contribution an overview is given of the basic approaches for the modeling and parameterization of

turbulence in the atmospheric boundary layer. Emphasis has been given to the treatment of atmospheric turbulent mixing in models with a horizontal spatial grid distance of order 10–100 km, a vertical grid distance of 10–100 m, and resolving time scales of order 10 min or larger. The treated approaches are in use in atmospheric models for the forecasting and study of weather, climate, and air quality on various domains (from the mesoscale to regional and global domains). Some of the approaches can be adapted for turbulence above the boundary layer, such as turbulence in clouds or in elevated shear layers. However, important exceptions have been documented in the literature when so-called 'mesoscale processes' have their influence. This may occur, for instance, when extensive fields of stratocumulus are present or in the case of deep cumulus clouds and thunderstorms.

Generally still work needs to be done before we have a full understanding of the complexity of atmospheric turbulence and before we have a more unified treatment of turbulence on the different scales which occur in nature (Holtslag et al., 2013). A better understanding of atmospheric turbulence hopefully also contributes to our capability in refining and unifying the turbulence parameterizations for modeling of the atmospheric boundary layer in response to the different type of surfaces which are found in reality. The current text can only be

seen as a rather broad overview of the approaches in use. Details can be found in the items in the References as well as in the scientific literature.

Introduction

We usually refer to *in situ* measurements as those made from some platform anchored to the surface, or in the case of the deep ocean from a ship or buoy. Instruments located on the surface but sensing the atmospheric boundary layer (ABL) remotely are not included. Over land the ABL reaches a height of between 1 and 3 km during the day, collapsing to a few hundred meters at night; the marine boundary layer is typically 500 to 1000 m day and night. The region sampled by *in situ* techniques is mainly in the atmospheric surface layer (ASL). This corresponds roughly to the lowest 10% of the ABL, and its characteristics are influenced strongly by the nature of the surface.

In situ measurements provide data for operational weather forecasting, environmental monitoring, validation for models and remotely sensed observations, and various research topics. The latter include studies of atmospheric structure and transport processes, agricultural and forest meteorology, pollution and climate change. Most applications require measurements of the state variables (temperature, humidity, and pressure), wind speed and direction, incoming and outgoing radiant energy, rainfall, and evaporation. Determination of the fluxes of sensible and latent heat, and of momentum, is also a critical objective of many *in situ* measurement programs.

This article first outlines the theoretical framework of the ASL, which often influences the observations required, and then the sensors commonly used to make the measurements. This is followed by descriptions of a few different types of field site and some practical aspects of deploying instruments and recording the data.

The Atmospheric Surface Layer

To set atmospheric transfer processes within a framework of classical fluid mechanics and thermodynamics, the starting point has been a flat and uniform earth's surface. Many experiments have taken place over such 'ideal' or one-dimensional sites. This article provides a brief and necessarily simplified account of the results, to introduce the quantities whose measurement is considered here. Full details can be found in the works listed under Further Reading.

The defining characteristics of the ASL are its buoyant stability, the vertical variation (or 'profiles') of wind speed, temperature, humidity, and the related vertical fluxes. The latter (so-called eddy fluxes) are given by

$$\tau = -\overline{\rho w' u'} \quad \text{(the flux of momentum, or surface stress),} \quad [1a]$$

$$H = \rho C_p \overline{w' \theta'} \quad \text{(the flux of sensible heat), and} \quad [1b]$$

$$E = \overline{\rho w' q'} \quad \text{(the flux of latent heat, or evaporation)} \quad [1c]$$

ρ and C_p are density and isobaric specific heat of air, w', u', θ' and q' are fluctuations from the mean of vertical and horizontal wind, and of temperature and specific humidity. The overbar indicates a time average of the particular product. Within the ASL over a uniform surface, the fluxes may be assumed constant with height.

The most common measure of thermal stability is based on the relative importance of mechanical and buoyant forces in production of turbulence kinetic energy (TKE); i.e. some function of the ratio of eqn [1a] divided by eqn [1b]. Defining a scaling velocity $u_* = (\tau/\rho)^{1/2}$ and a buoyancy parameter g/T , where g is gravity and T absolute temperature, these form a length scale $L = -u_*^3 / [\kappa(g/T)w'\theta']$; κ is a constant (≈ 0.4). The Monin–Obukhov similarity theory (MOST) adopts the hypothesis that, at height z in the boundary layer, flux–gradient relationships and turbulence parameters are universal functions of z/L . These MOST assumptions have been verified by many field experiments.

Wind increases with height in the surface layer while temperature decreases during daytime and increases at night (the nocturnal inversion) in response to the sign of the surface heat flux. MOST has nondimensional forms for the vertical wind and temperature gradients:

$$\phi_m = \frac{\kappa z}{u_*} \frac{\partial \bar{u}}{\partial z} \quad \text{and} \quad \phi_h = \frac{\kappa z}{\theta_*} \frac{\partial \bar{\theta}}{\partial z} \quad [2]$$

respectively, where ϕ_m and ϕ_h are functions of z/L , and $\theta_* = \overline{w'\theta'}/u_*$ is a scaling temperature. As an example, the variation of wind speed with height is given by integrating the first of these gradient equations, to obtain

$$\bar{u}(z) = (u_*/\kappa) [\ln(z/z_0) - \psi_m] \quad [3]$$

The integration constant, z_0 , is known as the surface roughness length, and ψ_m is a stability function. It follows that the wind variation with height is roughly logarithmic (exactly so in neutral conditions), and this is also true of the scalar quantities, $\bar{\theta}$ and $\bar{q}$. Finally, we note that the relationship between fluxes and gradients can be expressed in terms of a turbulent diffusivity,

$$F_\chi = -K_\chi \frac{\partial \chi}{\partial z} \quad [4]$$

where F_χ is the flux of constituent χ (momentum, heat, or a trace gas) and K_χ is its turbulent exchange coefficient, obviously a function of z/L .

Atmospheric Sensors

General Characteristics

There are often several choices of sensor for each variable, the most suitable for a particular application depending on several factors, including the accuracy and resolution required, frequency response, and overall convenience of operation. Sensors evolve continuously in the research environment,

either testing new physical principles of measurement or else to quantify some newly significant entity (e.g., a 'greenhouse' gas).

Considerations of frequency response highlight two categories of sensor, which we may call slow and fast. Atmospheric variables fluctuate on time scales from below 0.1 s to several hours. Time-averaging (over 15–30 min) is often required to reduce unsteadiness, so slow-response sensors are adequate to determine basic mean variables, such as $\bar{u}$, $\bar{q}$, or $\bar{\theta}$, and their vertical profiles. A sensor responds to a step change exponentially, the time taken to reach $(1 - 1/e; \sim 0.632)$ of the final value being its time response. A slow sensor may have a time response of many seconds. Fast sensors are required when the turbulent fluctuations themselves are of interest, either for studies of atmospheric structure or to determine the surface fluxes by measuring w' , u' , θ' , q' in eqn [1]. For this, frequency response of at least 10 Hz is needed.

The following sections describe first the most common slow-response sensors for atmospheric variables, and then some fast-response instruments. Figure 1 shows an array of instruments mounted at the top of a 30 m tower, part of the Ozflux network (see below). Sensors described in the text are identified by their letter.

Temperature

Atmospheric temperature can be measured with mercury-in-glass thermometers (still used operationally by weather observers), platinum resistance thermometers (PRTs), thermistors, and thermocouples. The last three lend themselves to automatic data logging. PRTs are very stable, and with careful calibration can achieve an accuracy of about 0.01°C. Thermocouple systems have low output voltage, and for absolute measurement require a reference 'cold' junction. Thermistors are semiconductor devices with higher sensitivity to temperature changes than either of the above, but at the expense of

non-linearity and greater self-heating than platinum elements. Formerly, they were prone to uncertainties of stability and calibration, but interchangeability of $\pm 0.1^\circ\text{C}$ is now possible.

Both thermocouples and PRTs can be easily configured for differential measurement, which can improve accuracy when measuring profiles or the wet-bulb depression of a psychrometer (see the next section). To reduce errors from solar radiation, these thermometers are ideally mounted inside a double-wall heat-reflecting shield and have ambient air drawn over them (A in Figure 1).

Humidity

Atmospheric humidity is variously specified by the partial pressure of water vapor (e , in hPa), vapor density ($g\ m^{-3}$), specific humidity (q , g/g of moist air), or relative humidity ($RH = 100e/e_s$). The relationship between them can be found in standard texts. e_s is the liquid water saturation vapor pressure at air temperature, given approximately by the empirical equation

$$e_s = 6.106\{\exp[17.273T/(T + 237.3)]\} \quad [5]$$

where T is Celsius temperature. At a particular ambient humidity, reducing air temperature reaches a point on the $T - e_s$ curve (eqn [5]) where the air is saturated. This gives us the principle of the dew point hygrometer. Its central component is a mirror maintained, by optical and electronic feedback, at the temperature where moisture or ice just condense on its surface. It is often considered an absolute instrument, and used as a secondary standard to other sensors.

The traditional instrument for atmospheric humidity measurement is the psychrometer, consisting of a pair of thermometers, one being covered with a moist wick. Air drawn over the thermometers evaporates the moisture, cooling the wick until the evaporation rate is in equilibrium with the vapor content of the air. For given humidity this wet-bulb depression,

Figure 1 An array of meteorological research instruments at the top of a 30 m tower, part of the 'Ozflux' long-term climate monitoring network in Australia. Photo: © Frank Bradley.

$(T - T_w)$, is known from thermodynamic theory, leading to the psychrometer equation. The form specified by the World Meteorological Organization (WMO) for the Assman psychrometer (a particular design of instrument with mercury-in-glass thermometers) is

$$e = e_s - 0.000\,653 \times (1 + 0.000\,944T_w)(T - T_w)P \quad [6]$$

where e , e_s , and atmospheric pressure, P , are in the same units. With PRTs in a differential bridge, $\pm 0.01^\circ\text{C}$ is possible for $(T - T_w)$. It is crucial to provide adequate airflow over the thermometers to ensure full depression. With care, accuracy of 0.05 g kg^{-1} is possible. For Assman psychrometers, 0.20 g kg^{-1} is more realistic.

Thin-film polymers which absorb or desorb water as the relative humidity changes afford a simpler humidity sensor. The polymer forms the dielectric of a capacitance in a circuit which provides an output proportional to relative humidity. Early instruments often failed at very high humidity, but recent developments have overcome this problem and have greatly improved their accuracy and stability. Conversion to mixing ratio, specific or absolute humidity requires the air temperature around the dielectric, usually measured with a colocated PRT. These temperature/RH sensors are screened and ventilated in the same way as a psychrometer. The best accuracy quoted is around $\pm 0.3\%$ RH (or $\pm 0.05\text{ g kg}^{-1}$ at 20°C and 70% RH).

Wind Speed and Direction

For average wind speed and/or direction over some time period, cup (or propeller) anemometers and wind vanes are usually the most convenient. Operational designs must withstand continuous exposure to stormy conditions, but there are also 'sensitive' instruments intended for research work. Apart from mechanical strength, the difference is reflected in their starting speed and distance constant (response time converted to run of wind). A sensitive cup anemometer will start from rest in a breeze of 0.3 m s^{-1} and have a distance constant less than 1 m .

For best accuracy (typically 1%) cups must be calibrated individually, although calibration in the steady horizontal flow of a wind tunnel can lead to uncertainty. In a gusty wind, cup anemometers overestimate for two reasons: the rotor responds more quickly to an increasing wind than to the reverse, and, in a wind gust with a vertical component, shielding by the upwind cup is reduced. A propeller has poor 'cosine' response (to off-axis wind direction), but the error is usually minimized by mounting it on the front of a wind vane. A cup-anemometer-wind-vane pair are often mounted at opposite ends of a horizontal bar (B and C in Figure 1).

Pressure

A knowledge of mean atmospheric pressure in the ASL is often needed, in eqn [6] for example, to calculate air density in eqn [1], and to convert between the various definitions of humidity. Pressure varies with elevation above sea level and slowly with synoptic changes. For most purposes, the pressure reported at 3-hourly intervals by the nearest weather forecast station is adequate. The WMO target accuracy for pressure measurement is $\pm 0.1\text{ hPa}$. It is read from either the traditional mercury column barometer or an accurate aneroid instrument.

Rainfall

Rainfall, particularly during convective storms, is perhaps the 'patchiest' of all meteorological variables. Single point measurements are generally less relevant than area averaged values, which may be estimated over land with a network of surface rain gauges. At sea this is not feasible, and while spatial rainfall patterns may be obtained by shipmounted radars these must be calibrated by a surface measurement.

Traditional rain gauges measure the rain falling into a funnel of known area. For automatic recording either a weighing system is used or a tipping bucket rain gauge. In this, the funnel discharges to a pair of buckets in a seesaw arrangement which flips over at every 0.1 mm of rainfall. Another system, often used on ships, has a reservoir which fills to its capacity (about 50 mm of rain), when it siphons automatically and starts filling again. An electronic sensor keeps track of the level of water in the reservoir. All funnel gauges lose catch in strong winds, when the gauge deflects airflow so that raindrops are carried past the funnel. The siphon gauge also misses rain while the instrument is siphoning.

Optical rain gauges (ORGs) measure rainrate by detecting raindrops falling through an optical path. One system measures extinction of a light beam by the raindrops; another measures the intensity of scintillations caused by raindrops passing through the beam from a light-emitting diode. Rainfall amount is obtained by integrating the rainrate. ORGs must be calibrated against a funnel gauge in natural or simulated rainfall.

Disdrometers are primarily intended for the measurement of drop size and drop distribution in rainfall. The most usual is an acoustic device which converts the sound of impact of raindrops hitting the sensor surface into an electrical signal related to the size of the drop. Continuous recording of the size and number of drops provides a time series of rainrate and total rainfall by integration.

The above rain gauges can handle rainrates to around 200 mm h^{-1} . This would be an extreme tropical storm; a heavy rainstorm in midlatitudes might produce instantaneous rain rates of 50 to 100 mm h^{-1} , but more commonly rain rates over land are between 1 and 20 mm h^{-1} . They are generally unsuitable for the measurement of precipitation falling as snow. However, because of its importance in the hydrological cycle in many regions, it is usual to estimate the water equivalent of snowfall, for example by measuring the average depth of fresh snow cover and its density.

Trace Gas Measurement

Measurement of minor constituents of the atmospheric boundary layer is increasingly important for studies of climate change (the 'greenhouse effect'), and monitoring of air quality. Applications include measuring emissions from engine exhausts and refineries, industrial stacks, agricultural emissions, and vegetation to atmosphere CO_2 exchange. Species of interest include CO , CO_2 , HF , N_2O , NO , NO_2 , CH_4 , SO_2 , NO_x , NH_3 , and other hydrocarbons and organic compounds. Accurate determination of both concentrations and fluxes are required, the former for regulatory purposes and the latter for studies of the emission process.

Chemical analysis and gas chromatography were some of the earliest techniques used, but are not convenient for

automatic recording. Infrared gas analyzers (IRGAs) have also been used for absolute measurement of CO₂ and some other atmospheric trace gases. The IRGA measures differential infrared absorption between a pair of cells containing the air sample and a reference gas (or between separate air samples for gradient determination). Originally intended as bench instruments, they are sensitive to vibration and in the field must be installed in a shelter with air samples drawn in through tubes.

Spectrographic methods have also been introduced, the most common being Fourier transform infrared spectroscopy (FTIR). Essentially, the instrument is a scanning interferometer which measures infrared spectra at high resolution over a broad spectral range, measuring all frequencies in the signal simultaneously, and resolving those required with the Fourier transform. Also developed as a laboratory technique, it has been adapted for field use, able to monitor species at very low concentrations (parts per billion of volume). Two configurations are employed: either an open atmospheric path is used, often folded to lengths up to 1 km, or the air is drawn through tubes to an internal measurement cell. Advantages of the open path are that it is noninvasive and that it affords spatial averaging. The internal system permits better temperature and pressure control, and reference to calibration spectra.

Trace gas profiles can be obtained by drawing air continuously from several levels through separate tubes, switched with valves sequentially through either the IRGA or FTIR. With the gradient of a particular constituent determined this way, its flux can be inferred from eqn [4], estimating the exchange coefficient from flux and gradient measurements of some easier quantity (e.g. sensible heat).

Fast-Response Instruments

Fast-response instruments are needed for studies of the turbulent structure of the boundary layer, and for eddy flux measurement. For the wind components, heated wire or film sensors have been used in the field, but poor stability limits their accuracy. Nowadays the usual sensor for turbulent wind measurement is the sonic anemometer (sonic for short), which obtains the wind component, V , along a fixed path length, d , by measuring the transit time of acoustic signals traveling in opposite directions (D in Figure 1). Then $V = c^2(t_2 - t_1)/2d$, where c is the velocity of sound in air. The earliest sonics determined this time difference directly or by measuring phase shift, but had the weakness that c^2 depends on temperature and humidity. Most instruments now use an alternative expression, $V = d(1/t_1 - 1/t_2)/2$. Different designs use various arrangements of the three paths needed to determine the total wind vector. Frequency response depends on the size of the sensing volume, a compromise between the conflicting needs for compactness and minimal flow distortion; d is typically 10–20 cm.

An internal microprocessor determines t_1 and t_2 for each path, and outputs wind components on orthogonal axes. Separate determination of t_1 and t_2 also enables fluctuations in virtual temperature to be obtained from the speed of sound. Then momentum and heat fluxes are calculated with eqns [1a] and [1b]. Temperature fluctuations can also be measured independently with a fine wire, usually of platinum, mounted in the yoke of the sonic; however, it is vulnerable to damage from rain and wind-blown debris.

Measurement of humidity fluctuations are usually based on absorption of either infrared (IR) or ultraviolet (UV) radiation by water vapor. IR instruments usually have a broadband source separated from a detector by an open path of physical length similar to that of the sonic vertical path. A rapidly rotating chopper wheel alternately introduces a pair of narrow pass interference filters into the beam, one at a strong H₂O absorption line (e.g. 2.61 μm) and the other at a nearby wavelength (e.g. 3.69 μm) of negligible absorption. This 'differential' scheme helps compensate for instabilities in the system, such as variations in source intensity. Some IR instruments add another filter at a CO₂ absorption line (e.g. 4.22 μm), to obtain both fluxes simultaneously (E in Figure 1).

The UV instruments detect absorption at the Lyman- α emission line of atomic hydrogen (121.56 nm) or from krypton (116.49 and 123.58 nm). These lines are strongly absorbed, providing good signals with a separation of only 1 cm between the source and the detector. Both types have long-term stability problems, but these are not serious for the measurement of fluctuations over periods like 15–30 minutes. Neither instrument is normally used for absolute measurement. The humidity sensor must be mounted as close as practicable to the sonic without increasing flow distortion. Formulae are available to correct for loss of correlation by lateral separation of the two instruments.

Fluctuations of static pressure are of interest in turbulence studies, where correlations like $\overline{w'p'}$ represent the transport of TKE by pressure fluctuations. p' is difficult to measure because any probe inserted in the flow may produce dynamic pressure fluctuations which mask those of static pressure. Instruments for this measurement remain research prototypes.

In principle, if a suitable infrared absorption line and fast-response sensor can be found, trace gas fluxes can be measured by the eddy flux method. Some IRGAs respond rapidly enough to measure eddy fluxes, with allowance for the time lag and frequency damping introduced in the air lines. When measuring trace gases, CO₂ and to some extent H₂O by eddy flux, account must be taken of fluctuations of density due to the presence of heat fluxes (the so-called 'Webb effect'). The corrections can be of the same order as the measured flux.

Radiation Sensors

General

The radiant energy flux to and from the earth's surface comprises the solar (or short-wave) component in the wavelength band 0.3 to 3 μm , and the terrestrial (long-wave or infrared) component from 3 to around 50 μm . They are measured with a pyranometer and a pyrgeometer respectively. These instruments are physically similar, both accepting broadband radiation through a hemispherical dome of appropriate spectral transmissivity.

Radiation observations can be conveniently discussed in the context of the balance of heat energy at the surface over flat terrain. If R_S and R_L are downwelling short-wave and long-wave radiative energy (W m^{-2}), T_S (K) is surface temperature, G_S is heat flux into the surface, and H and λE the turbulent fluxes,

$$(1 - \alpha)R_S + \varepsilon(R_L - \sigma T_S^4) - G_S = H + \lambda E \quad [7]$$

where α and ε are surface albedo and emissivity, σ the Stefan-Boltzman constant, and λ the latent heat of vaporization.

Short-Wave Radiation

Downwelling short-wave radiation at the surface has a component due to the direct solar beam, and a diffuse component scattered from atmospheric constituents and reflected from clouds. Upwelling short-wave radiation comes from reflection at the surface. Both can be measured with the pyranometer, facing either upward or downward (F and G in Figure 1); their ratio is the surface albedo. The pyranometer sensor is a blackened horizontal surface on which the radiation falls, bonded to a thermopile whose reference junction is the instrument body. Accuracy for the instrument is usually quoted as 2%. The direct solar beam can be measured with a pyrreheliometer. These are more accurate, but are generally unsuitable for operational use because they need to track the sun. Their main use is as calibration standards for working instruments.

The diffuse component is obtained with a 'shadow-band', set to shield the sensor from the direct solar beam. The position of the band is changed manually to follow the annual variation of solar elevation. Instruments have also been built with a rotating shadow band which alternately shields and exposes a fast-response radiation sensor, such as a solid state photocell. This system is less accurate, but useful on ships or other moving platforms.

Long-Wave Radiation

Pyrgeometers work by determining the thermal balance of the instrument itself. So as well as the thermopile output, the case and dome temperatures (T_C and T_D) have also to be measured. The long-wave energy passing through the dome is then derived from the pyrgeometer equation

$$R_L = V/s + \sigma T_C^4 + B\sigma(T_C^4 - T_D^4) \quad [8]$$

where V is thermopile output, s its sensitivity, and B an empirically determined constant (~ 3.5). Precision of the instrument using this equation is about 1.5% of the total long-wave flux. The third term on the right represents the effect of dome heating, and the second is the radiative flux contribution from the case of the instrument. The latter is usually the largest term, and is sometimes simulated with an internally generated voltage so that only one signal has to be recorded, instead of three. This, and the necessary assumption that $T_C = T_D$, increases uncertainties to at least 5%.

Net Radiation

Often the net radiant energy (all wavelengths) into or out of the earth's surface is required. This is the algebraic sum of the first two terms of eqn [7]. It can be measured using two pyranometers and two pyrgeometers, or more simply with a net radiometer. This consists of a pair of blackened plates, bonded to the opposite junctions of a thermopile to form a sensor about 25 mm square and 6 mm thick. It is protected by a pair of thin polythene domes, transparent to both short and long wavelengths, kept inflated with a flow of dry air. The symmetrical arrangement is mounted with the sensor

horizontal, measuring the temperature difference produced between the plates by downwelling and upwelling radiative energy (H in Figure 1). The quoted 5% accuracy is poorer than each of the individual instruments, but usually better than their combined uncertainties.

Surface Heat Flux

In eqn [7], G_s is roughly 10% of the net radiation over land and should not be ignored. It is usually measured with a soil heat flux plate, an encapsulated thermopile similar to the net radiometer sensor, buried horizontally at a shallow depth. Heat flux through the plate, assumed to be related to that in adjacent soil, generates a temperature difference between the opposite faces.

Absorption of heat into a water body is more complicated, because incoming short-wave radiation is distributed in depth with an extinction coefficient which depends on turbidity and wavelength. It can penetrate tens of meters into clear water. Incoming long-wave is absorbed within the top millimeter or so. Equation [7] may require additional terms for horizontal and vertical transport of heat (advection) by motion in the water.

Surface Temperature

The surface temperature, T_s , is usually measured with a narrow field of view IR radiometer in the 8–12 μm band. In daytime over land surfaces, T_s will normally vary over quite small distances because of variations in surface cover and topography. Thus, except where the surface is flat and uniform (e.g. bare soil, mown grass) a radiometer measurement from a height of even tens of meters will not be representative of the region. Radiometric measurements of sea surface temperature are more successful, because of the uniformity produced by mixing, and are particularly valuable for the validation of radiometers flown on satellites and aircraft. Corrections must be made for reflected sky radiation, measured with a second radiometer facing skywards, and the emissivity of the water at the particular IR wavelength must be known.

Types of Field Site

General

The physical nature of an experimental site, as well as the purpose of the observations, has a bearing on the instruments and methodology adopted. This section presents some characteristics of various field sites, and the consequences for useful measurement. We envisage midlatitude conditions; the same basic sensors and procedures are used in tropical and polar regions, perhaps modified to suit the extreme conditions encountered.

Flat, Uniform Landscape

As mentioned above, a theoretical framework for the one-dimensional ASL was derived from measurements at 'ideal' sites. These were located in vast regions with little topographic relief (Australian plains, the US Midwest, the Russian steppe),

and the actual observing site was a substantial area of completely uniform surface with short vegetation. Upwind changes in vegetation or soil moisture were avoided. A rule of thumb states that surface uniformity should extend upwind at least 100 times the height of measurement, with no trees or obstacles for many kilometers. Field campaigns in the 1960s rarely used towers higher than about 30 m, so the required fetch was of order 3 km. If application of the results from these experiments to another site is to be strictly valid, it should conform to the same criteria. In practice, useful results may be obtained from less favorable sites, provided the investigator is aware of the implications, and takes appropriate measures. For example, at the field site shown in Figure 2, wind blowing towards the camera would have both profiles and turbulence strongly perturbed by the belt of trees in the background. However the fetch to the left of the picture was clear for some kilometers, so data from that direction were acceptable. The sensor supports face that way and the equipment shelter is located well downwind of the towers.

Plant Canopies and Forests

Some of the earliest studies of the atmospheric surface layer were associated with agriculture and the relationship between climate and plants. Over short ground cover like pasture, the origin of profiles is the surface itself. For tall crops such as corn, orchards and forests, the concept of a zero displacement height, d , evolved, being the level near the top of the plant canopy where the neutral logarithmic wind profile has its origin. In eqn [3], the height z must be replaced by $z - d$. The value of d depends on the structure of the crop, but is usually about $\frac{3}{4}$ of its height.

Within the canopy, branches and leaves are sources and sinks for momentum, heat, moisture and CO_2 , which govern

the turbulent exchange processes. To obtain representative profiles of vertical fluxes and concentrations inside the canopy, measurements must be averaged in space as well as time. Canopy profiles merge with the boundary layer profiles near the top of the crop.

Sensors of the same type are used within the canopy as above, but are often smaller. Because of the three-dimensional wind environment, sonic anemometers are preferred over cups. Solar radiation penetrates the canopy and is absorbed and scattered at plant surfaces. Spatially averaged radiation profiles are sometimes obtained by moving the instruments along tracks at various levels through the vegetation. A wide range of specialized sensors have been developed for detailed study of canopy processes, energy exchange, water use, CO_2 uptake, and stomatal conductance, down to the scale of individual leaves.

Nonuniform Terrain

In the real world, the obstacles and surface nonuniformity so carefully avoided around 'ideal' sites are the normal condition, stimulating efforts to establish general rules to describe such complex terrain. Models have been developed for the two-dimensional internal boundary layers which grow downstream from a change in surface, and a sequence of such changes like the checkerboard pattern of agricultural land. There has also been some success in modeling wind flow over one- and two-dimensional hills.

Over such topography, observational problems escalate. A uniform site can be represented by a single vertical profile of instruments. To document the boundary layer over complex terrain requires many measuring sites and more sets of instruments. Their number, height and location depends on the

Figure 2 A micrometeorological research site in south-eastern Australia, set up by CSIRO Land and Water. The towers carry instruments to measure the profiles of wind, temperature, and humidity, the components of radiation, and eddy fluxes of heat, moisture and CO_2 , as part of a regional climate study. The tallest tower is 22 metres high; a shelter for recording equipment is seen to the right of the picture. Photo: © Greg Heath.

particular aims of the study, and must be to some extent intuitive. For example, is it enough to sample the extremes of the site (a hilltop and a valley), or must we also investigate sites in between?

Some guidance may be gained from simple modeling of the flow field. This, and the analysis of data from hilly sites, is often performed in a coordinate framework based on the streamlines of the flow. At any point in this curvilinear system, the x axis is along the local mean velocity vector, with the other two axes normal to it and to one another.

As the physical scale of topography increases, surface influence propagates higher into the ABL, beyond the range which can be studied exclusively with *in situ* techniques. This is where the combined strengths of *in situ*, remote sensing, and aircraft operations become important.

The Ocean

The ocean surface is notably horizontal, uniform and homogeneous. One-dimensional assumptions, turbulence theory, and the MOST relationships apply to the marine boundary layer. However, exchange between ocean and the atmosphere involves additional physical processes associated with the waves, surface currents, and heat transfer in the water

Most of the sensors described above are used at sea, but designed to survive the more hostile conditions. Wind, temperature, and rainfall measurements can be impaired by the presence of the ship. When practical, meteorological sensors are mounted on a jackstaff at the bow, in relatively clear air and ahead of spray from the ship's bow wave, or high on the mainmast with instruments duplicated on port and starboard sides. Psychrometers are seldom used because of the frequent need to wash salt from the wick. More usually, temperature and humidity are measured with the thin-film polymer package. Radiation instruments are mounted as high as possible, preferably in gimbals. The domes require daily washing to remove salt and particulates from the ship's exhaust. Upwelling radiation components are calculated from sea surface temperature, emissivity, and albedo.

Eddy fluxes are measured with the usual fast-response instruments, the sonic wind signals being corrected for ship motion measured with an inertial navigation system (INS), containing accelerometers, rate sensors, gyros, etc. The inertial dissipation technique of flux measurement (see [Further Reading](#)) is also used at sea, being less affected by flow distortion and ship motion. This also requires the fluctuations w' , u' , θ' , q' , but within the inertial subrange.

Over the ocean, a finite difference form of eqn [4], $F_\chi = C_\chi(\chi_S - \chi_A)$, is commonly used for flux calculation. C_χ is the exchange coefficient for variable χ and subscripts S and A refer to values at the surface and a reference height (usually 10 m). Values of C_χ have progressed from constants or simple functions of wind speed, to sophisticated forms embodying flux-gradient stability relationships and effects of sea state. These require iterative computer codes which calculate momentum, sensible and latent heat fluxes simultaneously (so-called bulk flux algorithms). Radiometric measurement of sea surface temperature is preferred, because skin temperature is the physically correct value to use for air-sea exchange. However, sufficiently accurate IR

radiometers are seldom available, so T_s is measured at some depth below the surface. Some flux algorithms take account of the difference between this (bulk) value and skin temperature.

Long-Term Observation Sites

Any description of *in situ* methods would be incomplete without reference to surface observations made worldwide by national weather services. Their principal purpose is for weather, aviation, and shipping forecasts, and increasingly for climatology, but they also provide data for community use. The variables recorded, and often the sensors used, are the same as those needed for research. Research experiments tend to record continuous time series at high resolution over relatively limited periods. Weather observations feature discrete data sampling (1–3 h, depending on the station), but on a regular and continuing basis.

The value of this data is enhanced by the careful documentation and quality control performed by the forecasting services, and the fact that instruments, sites and observational procedures conform to agreed international practice. Meteorological services do not adopt new instrument types without international comparisons, and avoid too many changes to preserve homogeneity of the climate record. The requirements for instruments (such as accuracy and calibration) and observation procedures are set out in WMO (1986).

Increasingly, automatic weather stations (AWS) are being developed and installed worldwide, taking advantage of technological advances in sensor development, computer capability, and communications. Data transmission from remote sites is possible by satellite or phone. Other advantages include more frequent sampling, exact timing, and avoidance of human error. This not only improves the forecast, but both the real-time and archived data are a quality resource for research.

A global network of stations has also been established for long-term measurement of land-atmosphere carbon, water, and energy exchange. Known as 'flux stations', they are operated by research institutions in various regions: 'Ameriflux', 'Euroflux', 'Ozflux' (Australia), etc. The principal measurement is of the eddy fluxes using the fast-response instruments described above, but a full suite of meteorological instruments is also maintained. Like the AWS, data are transmitted to base by a telemetry link.

Experimental Procedures

Platforms

Over land, instruments are usually mounted on a guyed mast or tower. To avoid distortion of the wind flow, these are as slim as possible without losing rigidity. Sensors are mounted at the end of arms, oriented in the direction of the prevailing wind. To accommodate winds from all directions, sensors are often duplicated on opposite sides of the mast. Equation [3] indicates that the profiles will be best defined with logarithmically spaced sensors.

Up to a few meters in height, the mast can be a simple tube, perhaps only 10 cm diameter. Taller masts are usually the climbable lattice type of triangular cross-section and about

30 cm side. Both types are shown in Figure 2, the near lattice tower being 22 m high; the practical limit is about 60 m. Beyond this, a major structure is necessary with a small elevator to transport equipment and personnel to the upper levels. Several such research towers have been built to heights around 300 m; the best known are by USA/NOAA at Boulder, the Dutch Meteorological Institute at Cabauw, and the Japanese Meteorological Agency at Tsukuba. More elaborate measures must be taken to extend the sensors far enough from these towers to minimize interference.

At shallow water sites, such as lakes and the coastal ocean, masts and research platforms have been built on the seafloor. Over the deep ocean, platforms are either ships or moorings. The difficulties of operating from ships have already been mentioned, particularly distortion of measurements by their bulk. Spar and toroidal buoys moored to the seabed also experience motion, but are less obtrusive. Toroids usually carry a frame for instruments to the height of about 4 m.

Networks of such moorings have been installed in climatically important regions, such as the tropical Pacific. They return data daily via satellite and can operate unattended for periods of six-months or longer. The most serious setback to reliability is not technical, but vandalism.

Figure 3 shows a unique and much-used facility called FLIP (Floating Instrument Platform) developed by the Scripps Institution of Oceanography. In effect a huge spar buoy 300 m long, it is towed on site and the lower part flooded so that it actually flips into the vertical. In this deployment, it is set up to measure the structure of the marine ASL. The photograph highlights the multiple sensors needed to determine variability with height, and the long boom to minimize the influence of the bulky platform.

Combined operation of aircraft with *in situ* platforms has proved highly effective. While surfacemounted instruments perform continuous time sampling, the aircraft complements this with spatial sampling over the surrounding region.

Figure 3 The floating instrument platform (FLIP) operated by Scripps Institution of Oceanography, La Jolla, CA, USA. FLIP is shown here set up for an investigation of the marine boundary layer by the Atmospheric Turbulence Laboratory of the University of California at Irvine. The boom is 20 m long and 12 m above the sea surface. It carries a vertical mast with instruments to measure profiles of wind and temperature, atmospheric turbulence and the fluxes of heat, moisture and momentum. Photo: © Carl Friehe.

Figure 4 A Twin Otter research aircraft operated by the US Department of the Navy, equipped with sensors to study wind, temperature, and humidity structure in the atmospheric boundary layer. Photo: © Carl Friehe.

Missions are often flown only 30 m above the surface, mostly using the sensors described above. **Figure 4** shows an aircraft equipped for boundary layer research; turbulent wind components are measured with pressure probes (C and F in **Figure 4**) corrected for aircraft motion with INS (I), temperature with thermistors or PRTs (A), mean humidity with a dew point hygrometer (B), and humidity fluctuations with Lyman- α or IR sensors (D and G). The latter may also be measured with a refractometer, which detects fluctuations of the radio refractive index of air, which depends on humidity, temperature, and pressure, in a microwave cavity. The advent of miniature electronics and the GPS navigation system has enabled development of miniature autonomous robotic aircraft, which can potentially play a valuable role in boundary layer studies.

Tethered balloons have been used to suspend instruments through the ABL, and may thus provide an alternative *in situ* platform within the height range of tall (300 m) towers. Their main advantage is portability and rapid deployment; an obvious difficulty is their instability. Instruments are attached to the tether cable at various levels although the actual height of measurement fluctuates with balloon motion. Eddy-flux measurements have been made from tethered balloons, the attachment for the flux package being designed to maintain its verticality and orientation. A development of this technique is the kytoon, a kite-shaped balloon which provides aerodynamic lift and better stability.

Sampling and Data Recording

When planning a series of observations it is important to consider the sampling required to achieve the aims of the project. We have seen that nonuniform terrain places demands

on spatial sampling. Sampling in time, even in the one-dimensional case, has several aspects. An instantaneous profile will be uneven because of turbulent fluctuations on many scales. Smooth profiles are obtained by averaging ensembles of many profiles over some period, which should be long enough to include most of the low frequency eddies, but avoid diurnal nonstationarity. In the surface layer, a period of 15–30 minutes is convenient.

This identifies the environmental time constraint to obtain realistic mean values. For sampling rate we consider the time response of the sensor. In the case of a ‘slow’ sensor (e.g. a platinum thermometer) this may be many seconds, much slower than the high-frequency end of the atmospheric spectrum. So the sensor rather than the variable determines the sample time; in practice 2–5 samples within the transducer time constant is sufficient.

Between the energy-containing low-frequency eddies of the atmospheric spectrum, and the high-frequency eddies which dissipate turbulence energy to heat, is a region known as the inertial subrange. This covers the spectral range from about 10 Hz to 0.1 Hz. Thus, to determine turbulence statistics and the eddy fluxes we need not resolve higher frequencies than 10 Hz. According to Shannon’s sampling theorem, to reconstruct the original signal without aliasing, this implies a sampling rate of 20 Hz. The fast-response instruments described above for w' , u' , θ' , and q' have been designed accordingly.

Dramatic improvements in computing speed and recording media, and reduced costs have revolutionized data recording practice. In the past it was usual to sample at the highest frequency required but record only average values. Time series of turbulent fluctuations filled racks of computer tapes. Now that data storage is no longer a restriction, all data can be archived at the original sampling speed, to enable reanalysis at

some later date. Ready availability of CD-ROM writers makes large data sets secure and portable.

Synopsis

This article covers remote sensing instruments including acoustic (sodar), radar wind profilers, radio acoustic sounding systems, and optical instruments (lidar). All these techniques are primarily ground-based. Airborne lidar measurements are also covered. Applications including air quality, research into boundary layer physics, mesoscale and storm scale meteorology, climate monitoring, and aviation weather sensing are considered.

Introduction

The planetary atmospheric boundary layer (ABL) is observed using a great variety of techniques both active and passive, employing radio, optical, and acoustic energy. A variety of instruments have been developed in response to the broad range of temporal and spatial scales of interest in the ABL and the large number of parameters that need to be measured. In this article we cover remote sensing instruments, that is, those that measure parameters of a volume of air at some distance from the instrument itself. Most ABL remote sensing is done from the ground, although some spaceborne or airborne instruments have some boundary layer applications. Generally, however, ABL observations require spatial resolution (horizontal and vertical) that is unavailable from instruments on satellites. We will discuss airborne lidar measurements.

Atmospheric quantities and constituents (winds, temperature, humidity, trace gases, etc.) interact with electromagnetic and acoustic radiation in different ways, but all have in common that they interact only weakly with such radiation. Therefore, a primary challenge in the development of remote sensing instrumentation is deriving useful data at low signal-to-noise ratios.

Remote sensing measurements of the boundary layer are used in a wide variety of applications. Air quality research and operational measurements for air quality, research into basic ABL physics, mesoscale and storm scale meteorology, climate monitoring, and aviation weather sensing are important applications.

Interesting boundary layer motions occur on scales ranging over at least six orders of magnitude, from the dissipative scale of order 1 cm to tens of km, although most measurements are of scales between a few meters and a few kilometers. The boundary layer itself ranges from approximately 100 m to 3 km deep, and the motions that transport energy and momentum are on the scale of the ABL depth. The most important horizontal scales are those of the underlying terrain and variations of pollutant emissions. Different instruments and observational strategies are required to measure different scales even over the range between nocturnal boundary layers (~100 m) and convective boundary layers (~1 km).

The remainder of this article discusses the quantities to be measured in the ABL, then covers the variety of instruments and techniques available. While some ABL remote sensing instruments are commercially available, many are custom-built for research use. An article such as this will necessarily

omit some specific instruments, so we hope to provide a useful overview of instruments and techniques and their underlying principles.

Active and Passive Remote Sensing

Boundary layer remote sensing instruments fall into two major categories, active and passive. Active instruments emit electromagnetic or acoustic radiation and detect the portion of that radiation returned from the target volume of the atmosphere. Passive instruments, on the other hand, detect radiation from natural sources that is scattered or modified by the atmosphere. This article covers only active instruments.

Active instrument categories are radar, lidar, and sodar (q.v.). All are similar in principle, as reflected by their names, which once were acronyms. In the simplest case, radars, lidars, and sodars emit pulses of radio frequency, optical, or acoustic radiation, respectively, and detect the very small fraction of each pulse that is backscattered by the atmosphere. The characteristics of the backscattered radiation carry information about the atmosphere, and that information differs depending on the wavelength and type of radiation and therefore the ways in which the radiation interacts with the atmosphere. These interactions are referred to as *scattering mechanisms*. The primary scattering mechanisms relevant to the ABL are Bragg scatter from the fluctuations of the acoustic and radio refractive index for sodar and radar respectively; Rayleigh scatter from small objects for radar and from air molecules for lidar; Mie scatter from aerosols for lidar; and Raman scatter for Raman lidar. The distance (range) of the volume from which the radiation is scattered is most often measured from the round-trip travel time of the radiation pulses.

Quantities to be Measured

In the boundary layer, measurements of winds, turbulence, temperature, humidity, trace gases, and aerosol content and properties are needed. In addition, derived quantities such as mixing height (ABL depth) are useful. Different instruments and techniques have been developed to address each of these quantities. The graphical presentation of patterns of measured quantities, made possible by the continuous nature of most remote sensing measurements, has led to important insights.

For wind measurements, radar wind profilers, Doppler sodars, and Doppler lidars are used. Given sufficient temporal and spatial resolution, these instruments can also measure turbulence.

Temperature is remotely sensed by radio acoustic sounding systems (RASS), a hybrid radar and acoustic technique, and by rotational Raman lidars. In RASS, a wind profiler measures the speed of a propagating acoustic disturbance and the temperature is derived from that speed of sound.

Humidity or water vapor concentration measurements are made by differential absorption lidar (DIAL) or Raman lidar techniques. The DIAL technique at different wavelengths can also measure concentrations of trace gases such as ozone.

Aerosol backscatter and extinction are measured by backscatter lidars. Most Doppler lidars and DIALs also produce backscatter measurements.

Mixing height or ABL depth, a key quantity for most ABL operations and research, can be detected by several techniques. Wind profiling radar reflectivity exhibits a peak at the ABL top, which has been used extensively to detect mixing height. Aerosol, humidity, trace gas, turbulence, and temperature profiles from lidars can also indicate the ABL depth.

Integration of sensors can yield better results than individual sensors alone. The entire boundary layer cannot always be covered with sufficient resolution by a single sensor, so combining profiles from, for example, a sodar and a wind profiler may be useful. This is especially true for mixing depth over the full diurnal cycle.

Techniques

Sodar

Sodars emit sound waves and detect the backscattered acoustic signal to measure atmospheric structure and, in the case of Doppler sodars, velocity. Sodar was gradually developed during the 1960s and came into routine use in the 1980s. Today sodars are used for operational monitoring of winds above normal tower heights at power plants and other pollution sources, and are commonly included in boundary layer research campaigns. A typical sodar is shown in Figure 1.

The simplest sodars measure only the intensity of backscatter from the turbulent structure of temperature and velocity in the boundary layer. The time and height variations of turbulent structure can be interpreted to elucidate a variety of boundary layer phenomena. Doppler sodars add the capability of measuring the Doppler shift of the backscattered acoustic signal and convert the Doppler shift to a velocity along the direction of the acoustic beam. Beams in different directions are emitted and detected sequentially to produce the full three-dimensional wind vector. Three or five beams are commonly used; in the case of three beams two are separated by 90° in azimuth and aimed $15\text{--}20^\circ$ off the zenith, and the third is a vertical beam; in the case of five beams four are separated by 90° in azimuth and the fifth is again vertical. Different beam directions are generated either by separate antennas or by a phased array allowing electronic beam steering.

Sodars generally measure in the lowest few hundred meters of the atmosphere, although some are capable of maximum ranges of a kilometer or more. The limitation on range is due to

Figure 1 Sodar with three separate antennas at a power plant in Germany. Photo courtesy of METEK Mestechnik GmbH.

the rapid attenuation of the acoustic signal in the atmosphere, which is highly variable and may be as much as 40 dB km^{-1} . Sodars operate at frequencies between a few hundred hertz and a few kilohertz. The operating frequency is chosen to optimize among range resolution, maximum range, and antenna size. The minimum sampling time on each beam is determined by the maximum range and the sensitivity, and is normally a few seconds. A few tens of samples are commonly averaged to improve the quality of the wind estimates, so the 3D wind vector is available every 10–30 min. Range resolution varies from a few meters up to 20 m or so. Some sodars use multiple frequencies.

There are some hundreds of sodars installed at monitoring sites around the world, and several manufacturers provide off-the-shelf systems. In addition, at least tens of systems are in use by research groups.

Quality issues for sodar data include sensitivity to ambient noise and to noise from rain hitting the antenna. Sodars are also sometimes susceptible to ground clutter, strong spurious signals from nearby objects. Siting a sodar can be difficult because of concerns about the noise produced.

Radar

Specialized radars are an important category of boundary layer remote sensing instrumentation. Traditional weather radars rely primarily on scattering from hydrometeors, although modern systems have sufficient sensitivity to sense clear-air returns. Boundary layer remote sensing is most commonly done with wind profiling radars (profilers) (q.v.), which have comparable sensitivity to weather radars at much lower cost, but have reduced scanning flexibility and coarser time resolution. A boundary layer profiler is shown in Figure 2.

Boundary layer wind profilers evolved from mesosphere-stratosphere-troposphere (MST) radars (q.v.), which were developed for investigations of the middle and upper atmosphere. The original impulse for boundary layer profiler development was the need to fill in wind measurements at heights below the minimum range of the MST radar. The first

Figure 2 915 MHz wind profiler of the NOAA Aeronomy Laboratory at Chebogue Point, Nova Scotia for the 1993 North Atlantic Regional Experiment. The cylinders are the RASS acoustic sources. The flaring structure is the clutter fence, designed to reduce ground clutter. The 2×2 m phased array antenna is at the base of the clutter fence inside the structure.

ABL profiler was developed at the NOAA Aeronomy Laboratory by Warner Ecklund and colleagues in the mid-1980s. Since then, a large number of similar profilers have been built and a number of variations have been explored. Most ABL profilers are pulsed Doppler radars, but a few frequency modulation continuous wave (FM/CW) systems are also in use.

Boundary layer profilers operate at about 915 MHz in North America and 1290 MHz in Europe and Asia, the frequency being determined by the availability of bandwidth in the region. The basic beam geometry is similar to that described above for sodars. All profilers have Doppler capability. Beams in different directions are emitted and detected sequentially to produce the full three-dimensional wind vector. Three or five beams are commonly used; in the case of three beams two are separated by 90° in azimuth and aimed $15\text{--}20^\circ$ off the zenith, and the third is a vertical beam; in the case of five beams four are separated by 90° in azimuth and the fifth is again vertical. Different beam directions are generated by separate antennas or by a phased array allowing electronic beam steering. An individual sample is acquired approximately once per second, and 10–50 samples are averaged before going on to the next beam. An estimate of the full 3D wind vector is typically available every 1.5–5 min, but usually these are also averaged to reduce noise, so the most common time resolution is 20–60 min.

Wind profilers measure 3D winds by detecting the motion of refractive index fluctuations in the clear air at the scale of half the radar wavelength. In the boundary layer, the refractive index fluctuations are dominated by the fluctuations of humidity. Therefore the intensity of the backscattered radar signal is essentially proportional to the humidity gradient and the turbulence intensity. This relationship is used to find the height of the convective boundary layer. Wind profilers are generally not suitable for measuring the structure of the stable ABL because their minimum range and range resolution are too large. Estimates of turbulence intensity are made either from

the variance of the time series of wind velocities in the vertical beam, from the width of the Doppler spectrum, or a combination of the two.

Boundary layer profilers generally use range resolution of 60–100 m depending on the choice of operating modes. Better resolution results in less maximum range due to reduced average power. The minimum range of most ABL profilers is 100–150 m, and the maximum range depends strongly on the ambient conditions. The maximum range is always sufficient to see the entire convective boundary layer over land, at least 4 km in summer and in the tropics, but as little as 1 km in continental winter when humidity and turbulence are both lacking. As previously mentioned, time resolution can be as good as a few minutes, but generally is 20 min or more. An example of data from a boundary layer profiler is shown in **Figure 3**.

Most boundary layer profilers are used in field campaigns for basic boundary layer physics and air quality research. Some are in fixed or long-term deployments. Winds from profilers are used to define transport of pollutants and to explore the flow patterns due to coasts and storms. The convective boundary layer height derived from profilers is a key quantity in analysis of pollutant plumes from urban areas and power plants. Winds and ABL height from networks of profilers have been used for basic studies of the spatial and temporal structure of the boundary layer. Profilers have also been deployed for climate monitoring and for monitoring of the winds near airports.

While profilers are designed to detect backscatter from the clear air, they are also sensitive to other types of scatter. Birds, insects, and hydrometeors are important scatterers and sometimes dominate the clear-air signal. Most profiler systems are equipped with hardware and software for quality control, but users of profiler data must take care to avoid misinterpretation of contaminated data. Another quality issue with profiler data is so-called ground clutter, that is, signals from ground-based

Figure 3 Wind and mixing height data from a boundary layer wind profiling radar at Houston Southwest Airport, Texas. Wind speed is shown by the length and color of the arrows; wind direction is along the arrow with north at the top of the plot. Circled dots are mixing height derived by an observer from the pattern of radar reflectivity.

objects (e.g., trees) that may be seen by a sidelobe of the antenna. As with any radar, interference from other radio sources may be an issue.

In addition to the well-established profilers to which most of the above description pertains, several exotic radar systems have been built for ABL research. Such systems often use spaced-antenna or interferometric techniques. At least one FM/CW system exists that produces extremely high resolution pictures of the boundary layer.

Operational wind profiling radars operating at lower frequencies, including the 449-MHz profilers of the NOAA Profiler Network, have sufficient resolution for some boundary layer studies. Weather radars may also provide some useful boundary layer information.

Radio Acoustic Sounding Systems

RASS (q.v.) are often attached to wind profilers. In RASS, an acoustic signal is emitted with a wavelength one-half the radar wavelength (frequency 2–3 KHz for most ABL profilers). The radar measures the speed of sound, from which the (virtual) temperature can be straightforwardly derived to a reasonable degree of accuracy and precision (<0.5 K accuracy and precision for half-hour averages). A second type of RASS also exists as an accessory to sodars, in which case the radar is a simple continuous-wave type. The range resolution and minimum range of RASS are the same as those of the profiler or sodar to which it is attached, but the maximum range is limited by advection of the acoustic signal out of the radar beam when moderate to strong winds blow, and by the acoustic attenuation, which can be very large at typical RASS frequencies.

Lidar

Lidars are active remote sensing instruments that are well suited for ABL research. They measure many important quantities, such as wind speed, turbulence, aerosol backscatter and extinction, water vapor, other trace gases, and temperature; and they typically cover the entire depth of the ABL. Lidars use lasers to emit short light pulses into the atmosphere. The small fraction of the light backscattered by the atmosphere is detected by a receiver typically consisting of a telescope, photodetectors, and data acquisition electronics. For lidars used in ABL research the relevant scattering mechanisms are Rayleigh and Raman scattering from air molecules and Mie scattering from aerosol particles.

The first lidars were built in the 1960s soon after the invention of the laser and extensive work went into developing lidar remote sensing techniques. In the 1970s and 1980s, with the advent of lasers that could be tuned over a wide range of wavelengths, the application of lidars in atmospheric remote sensing became more widespread. The 1990s saw increased use of solid state lasers as lidar transmitters and a trend toward more compact lidar systems. This trend continued in the 2000s as robust, commercially available optical components, initially developed for the telecom industry, were increasingly utilized in lidar systems. Lidars that are in use today operate at wavelengths from the near ultraviolet to the far infrared regions of the electromagnetic spectrum. Most lidars are still prototype,

research-grade instruments. In recent years, however, a number of lidar systems, in particular aerosol and Doppler wind lidars, have been developed that can be operated unattended over extended time periods and lend themselves to long-term monitoring applications. A specific category of lidars, called ceilometers, are autonomous, turn-key instruments that are commercially available and have seen fairly widespread use for a number of years; however, their application is generally not research oriented. Ceilometers are compact, unattended, low-power lidars that are mostly operated at airports to routinely measure cloud base height.

Many of the lidar systems used for ABL research are installed on mobile platforms, such as trailers, ships, or aircraft, so they can be easily deployed in different locations. [Figure 4](#) shows a lidar system installed in a research aircraft. This aircraft typically flies at 3–4 km above sea level allowing profiling of the entire ABL with the downward-looking lidar.

In response to measurement needs, various types of lidars have been developed that are distinctly different in terms of the detection technique and scattering mechanism they employ. Most ABL lidars detect elastically backscattered light from air molecules and aerosol particles. Among this group of lidars one distinguishes direct detection lidars and heterodyne Doppler lidars. Direct detection lidars measure the intensity of the backscattered light, while heterodyne lidars use coherent mixing with a reference beam to detect the Doppler shift between the emitted and backscattered light. The Doppler shift is a measure of the radial wind speed along the lidar beam direction. By scanning the Doppler lidar beam using specific patterns, profiles of horizontal wind speed, direction, vertical velocity, and turbulence can be measured. Both direct detection and Doppler lidars can be used to infer information about aerosols in the ABL, particularly aerosol backscatter and extinction. A direct detection lidar that is used solely for this purpose is often referred to as a backscatter lidar. A High Spectral Resolution Lidar is a specific type of backscatter lidar that separates the atmospheric particulate and molecular return signals and is capable of providing independent measurements of aerosol backscatter and extinction profiles. DIALs are direct

Figure 4 Airborne, downward-looking ozone lidar of the NOAA Earth System Research Laboratory installed in a research aircraft.

detection lidars that emit laser light at two or more wavelengths. These wavelengths are chosen so that they are absorbed to a different degree by an atmospheric trace gas. If the absorption cross section of the trace gas is known, its concentration can be inferred from the intensity difference of the backscattered light at the various wavelengths. DIALs are most commonly used to measure water vapor and ozone concentration, but other trace gases, such as sulfur dioxide, nitrogen dioxide, ammonia, and various hydrocarbons, have been detected with DIAL as well. As an example of the kind of information a DIAL system can provide, Figure 5 shows a time–height cross section of ozone mixing ratio measured with an airborne ozone DIAL. The high ozone concentrations in the center of the plot indicate the extent of the urban pollution plume that had developed on 12 July 1995 over Nashville, Tennessee. In contrast to direct detection and Doppler lidars, Raman lidars detect the fraction of the emitted light that is Raman scattered by air molecules or trace gases. The Raman scattered light is shifted in wavelength, and the magnitude of the shift depends on the scatterer. Raman lidars are primarily used to measure humidity profiles by detecting the Raman scatter of water vapor molecules in the atmosphere. Raman lidars can also be employed to measure aerosol extinction from the Raman scattered light of oxygen or nitrogen molecules (for which the concentrations are known). Another important application of Raman lidar is the measurement of temperature profiles using the rotational Raman lidar technique.

Time and spatial scales of lidar measurements in the ABL vary depending on the measured variable and the type of lidar used. In the following, time and range resolutions are given that can be achieved with state-of-the-art, research-grade lidar systems. Profiles of aerosol backscatter can be measured with time and range resolutions as low as 0.1 s and 1.5 m, while wind speeds can be retrieved at resolutions of about 1 s and

30 m. The DIAL technique requires taking the derivative of the measured signals with respect to range. Therefore, higher signal-to-noise ratios are necessary than for wind speed or aerosol backscatter measurements, requiring longer averaging times and coarser range resolution. Time and range resolutions of ABL water vapor or ozone measurements that can be achieved with DIAL are on the order of a few seconds and several tens of meters, respectively. Due to the low Raman scattering cross sections, daytime Raman lidar measurements in the ABL generally require averaging over several minutes and yield range resolutions of about 100 m. At night, without interference from solar background light, water vapor measurements using the Raman technique are comparable to DIAL measurements in terms of their resolution. The maximum range of lidars used in ABL research is in most cases sufficient to cover the entire ABL and the portion of the free troposphere immediately above the ABL. The minimum range is typically on the order of a few hundred meters. With a scanning lidar the altitudes below minimum range can be probed by pointing the beam a few degrees above the horizon. Certain meteorological conditions restrict the useful range of lidar. Lidar measurements in or beyond optically thick clouds (such as ABL cumulus or stratus) or in dense fog are not possible because the lidar signals are scattered and absorbed within the first tens of meters. During precipitation events lidar operation is not useful and may be impossible.

The measurement capabilities of lidars make them valuable tools in many ABL research areas. Profiles of aerosol backscatter, humidity, trace gas concentrations, temperature, and turbulence measured with lidar can be used to infer the ABL height, which is a key parameter in ABL research. Due to the high time and range resolution that can be achieved with lidar it is possible to investigate turbulence statistics in the ABL, including third- and fourth-order moments. Their narrow beam width and shallow-angle scanning capabilities

Figure 5 Ozone cross section measured with an airborne ozone DIAL around midday on 12 July 1995 during a transect passing over the city of Nashville, Tennessee.

make lidars well-suited to provide detailed information about the shallow nocturnal ABL. Air quality research, in particular the distribution and transport of pollutants and fine particles, is another important application. Other research areas where lidar has made important contributions include the study of flows in complex terrain, the characterization of the wind field at wind farms, and the measurement of trace gas fluxes by using collocated DIAL and Doppler lidars.

Synopsis

The oceanic mixed layer (OML) mediates the exchange of mass, momentum, heat, and energy between the oceans and the atmosphere. As such, it plays a crucial role in long-term weather and climate. It is also important to the oceanic food chain, since the nutrient uptake into the euphotic zone from nutrient-rich waters below depends on the entrainment at the base of the mixed layer. This section provides an overview of the OML and the associated physical processes.

The oceanic mixed layer (OML) mediates the exchange of mass, momentum, heat, and energy between the oceans and the atmosphere. As such, it plays a crucial role in long-term weather and climate. It is also important to the oceanic food chain, since the nutrient uptake into the euphotic zone from nutrient-rich waters below depends on the entrainment at the base of the mixed layer. This section provides an overview of the OML and the associated physical processes.

Introduction

The OML, the ocean region adjacent to the air–sea interface, is typically tens of meters deep, and due to the fact that it is well mixed, the temperature and salinity (and therefore the density) are fairly uniform. The rapidly changing regions below these uniform regions of temperature, salinity, and density are called the thermocline, halocline, and pycnocline, respectively. The mixing is primarily shear driven, since the wind stress at the surface is the primary mixing agent, although at night significant convective mixing driven by the heat loss to the atmosphere takes place. The OML is heated near the surface by both short wave (SW) and long wave (LW) radiative fluxes, and deeper in the water column from solar radiation in the visible part of the spectrum penetrating into the OML. This solar heating produces a diurnal cycle that varies in importance and magnitude at different latitudes. The cooling, however, is driven from heat and evaporative losses at the surface. Seasonal variation of the OML due to radiative heating is also important, although its importance depends on the latitude.

The OML mediates the exchange of mass, momentum, energy, and heat between the atmosphere and the ocean and hence plays a central role in long-term climate and weather. Because of the high heat capacity of water (2.5 m of the upper ocean has the same heat capacity as the entire troposphere), and because the oceans compose over two-thirds of the surface of the globe, most of the solar heating on Earth passes through the OML. Oceans are heat reservoirs, gaining heat during spring and summer and losing it slowly during fall and winter, and therefore act like a flywheel in matters related to weather on timescales of weeks and longer.

The OML also plays an important role in the oceanic food chain. Primary production by phytoplankton is the first link in this chain. The need for an energy source in producing biomass

restricts primary production to the upper few tens of meters (the euphotic or photic zone), in which the solar insolation is strong enough to assist carbon fixation. The mixing at the base of the OML is also crucial to biological productivity. The OML is normally nutrient-poor and it is the injection of nutrients from the nutrient-rich waters below the seasonal thermocline that permits higher levels of primary productivity. In fact, it is the upwelling regions (which compose just a few percent of the world's oceans), where nutrient-rich waters are forced into the OML and brought into the photic zone, that provide most of the fish catch around the world.

Biological productivity is important from a climatic point of view over timescales of decades or more. Carbon fixing constitutes a biological pathway for removing some of the anthropogenic CO₂ introduced into the atmosphere. There also exists an inorganic pathway since there is a significant uptake of CO₂ in the cold subpolar oceans, some of which are also regions of deep and intermediate dense water formation. The ocean acts as an important CO₂ sink on the globe and accounts for a significant fraction of the 'missing' anthropogenic CO₂ input to the atmosphere. However, quantification of the magnitude of this sink requires accurate OML models coupled to accurate ecosystem and air–sea transfer models.

Finally, the OML constitutes the first link in the chain of oceanic pollution. Most of the pollution in the global oceans takes place in the coastal oceans through the OML, and therefore the fate of any pollutants accidentally or intentionally deposited in the OML depends on the mixing and dispersion in the OML.

Characteristics

An OML can be divided into four parts, the very thin but important molecular sublayer, a few millimeters thick; the wave sublayer, normally 2–6 m thick; the main bulk of the OML, 10–40 m thick; and the entrainment sublayer of about 5–10 m thickness. In deep convective OMLs, where the mixed layer depth is a few hundred meters or more, the fractions of the wave and entrainment sublayers are small. In a shallow diurnal OML, a few meters thick, the wave sublayer can be a large fraction. An active gravity wave field can damp out the diurnal modulation of sea surface temperature (SST) by wave-driven mixing through Langmuir turbulence or wave breaking processes.

The active turbulent mixed layer in the upper ocean is usually bounded below by a strong buoyancy interface, in the form of a layer with either a sharp decrease in temperature (seasonal thermocline) or a sharp increase in salinity (halocline) (or both). In either case, this layer (called a pycnocline) is stably stratified, and here, turbulence is damped by buoyancy forces. The transition region from active turbulent mixing to mostly quiescent layers below can be called a turbocline, in analogy with the thermocline. Normally, the turbocline coincides with the seasonal thermocline or halocline, but not necessarily both. During high precipitation events, a shallow brackish layer can form and the halocline and turbocline are at similar depth but the thermocline is much deeper. In the tropical western Pacific, a similar situation exists, leading to the so-called barrier layer that plays an important role in the transfer of heat from the ocean to the atmosphere in the tropics, by acting as a barrier to mixed layer deepening and entrainment of waters below the halocline.

An OML is mixed from both the top and the bottom. At the top, it is the winds, waves, and buoyancy fluxes that stir the fluid. At the bottom, it is the entrainment driven by large turbulent eddies in the OML that mixes the denser fluid from below into the OML. Wind-driven current in the OML also

causes strong shear at the base of the mixed layer; shear instability ensues, inducing Kelvin–Helmholtz billows, which thicken the buoyancy interface and hence decrease its resistance to erosion by turbulent eddies. In deep OMLs, it is these mechanisms at the bottom that are responsible for a majority of the deepening of the OML. In shallow OMLs, the surface-stirring processes due to gravity wave breaking and cellular motions are also important. Note that turbulent erosion tends to sharpen the pycnocline, while K–H billows tend to make it more diffuse.

Perhaps the most salient aspect of the OML in midlatitudes is its diurnal and seasonal variability. Figure 1 shows the typical seasonal cycle in midlatitudes. This seasonal variability in OML depth and temperature, and hence the heat content of the OML, is a prime factor in the air–sea exchange at these latitudes. The onset of spring warming restratifies the water column and once the shallow spring–summertime thermocline forms, its depth stays roughly constant. However, the formation period is heavily influenced by wind events at the time. Similarly, wind forcing controls the deepening of the OML at the onset of autumn cooling. During this time, the OML deepens episodically during intense storms that pass through the region, with significant assistance from cooling at the surface. Both sensible and latent heat fluxes are important in

Figure 1 Seasonal evolution of temperature in the midlatitude upper ocean. Shallow warm mixed layers during spring/summer alternate with cold deep ones during fall/winter.

cooling the ocean at midlatitudes, whereas it is principally the evaporative losses that dominate the air–sea exchange at warmer low latitudes and sensible heat loss at colder high latitudes. Precipitation events also play a role in mixing. Wintertime cold air outbreaks along the east side of continents lead to rapid OML deepening, a large heat loss from the ocean, and cyclogenesis in the atmosphere. At higher latitudes, the OML deepens more due to penetrative convection, and in subpolar regions, deep convection occurs. The OML structure in midlatitudes is affected by both salinity and temperature, whereas in subpolar and polar oceans, salinity plays an overwhelmingly important role in mixing, and in the tropics, the thermal structure in general predominates.

Diurnal variability affects the heat exchange on shorter time-scales and may play a role over long timescales as well. The intensity of diurnal modulation of the OML depth and temperature depends on the season. Generally, the modulation is stronger if the solar insolation is strong and winds weak. Longer daylight hours also lead to increased diurnal warming producing a latitudinal dependence. Precipitation, especially during the early morning hours, can lead to a stable fresh layer also enhancing diurnal warming. Thus during summer in subtropics, with longer days, higher insolation values reaching 1200 W m^{-2} , and light winds, can lead to a diurnal modulation of as much as $6\text{--}7^\circ\text{C}$. Under these extreme conditions, the surface layer no longer resembles a shallow mixed layer with very reduced (but still existing) turbulence, but instead an extremely shallow very stable layer. Turbulence itself is completely extinguished and molecular processes in addition to the absorption profile of solar radiation drive the temperature profile. This shallow layer is essentially uncoupled from the deeper residual mixed layer, and a diurnal current can form over the region where this condition occurs, as the surface water ‘slips’ over the deeper mixed layer. The depth of the diurnal mixed layer (and the resulting temperature structure) can also be affected by Langmuir circulation and turbulence. A part of the heat built up in the OML during the day is lost by nocturnal cooling, which drives a vigorous convection and mixing in the water column that normally mixes some of the heat gained into the seasonal mixed layer.

A major factor in OML dynamics in the equatorial regions is the presence of strong background currents in the vicinity of the OML. The Equatorial Undercurrent in the Equatorial Pacific is a typical example. It exists at depths ranging from 50 to 200 m and is an eastward-flowing current that produces a strong vertical shear, which has a major influence on mixing in the upper water column. In contrast, in midlatitude oceans, the principal balance is between the Coriolis terms and the stress divergence, and the currents are not continuously accelerated by a steady wind; instead a steady state is reached and an Ekman-like spiral is produced.

In ice-covered oceans, the ice mediates the exchange of momentum between the atmosphere and the OML. The principal balance in ice is between the Coriolis force, the wind stress at the top, internal stresses in ice, and the shear stress on the ocean at the bottom. This force balance determines the stress available for mixing under ice. In addition, ice growth and melting causes buoyancy fluxes that affect the OML below the ice. Stirring by deep ice keels is an important factor. The ice cover tends to insulate high latitude oceans from the cold atmosphere. However, it is not continuous and even in the

middle of winter, there exist narrow openings in ice, called leads, through which a substantial fraction of winter-time heat loss to the atmosphere at high latitudes takes place. **Figure 2** shows the mixing processes prevalent under leads.

There are striking similarities between the atmospheric boundary layer (ABL) over land and the OML. Under convective conditions, similar scaling laws hold in both turbulent layers. However, the most important difference between the OML and the ABL over land is the presence of surface waves at the air–sea interface that play an active role in its dynamics. The dynamical influence of the ground surface on the ABL is determined by its roughness and topography, which are invariant, whereas it is the effective roughness of the mobile sea surface that is constantly changing with the winds that is important in the OML.

Under neutral stratification, it is possible to find a region where the universal law of the wall scaling would apply: $q \sim u_*$, $l \sim z$, and $\varepsilon \sim z^{-1}$, $v_t \sim z$, where u_* is the friction velocity (square root of the ratio of the wind stress to the water density), q is the turbulence velocity scale, l its length scale, ε is the dissipation rate of turbulence kinetic energy (TKE), v_t the eddy viscosity, and z is the depth. Here, the mean shear is proportional to u_* but inversely proportional to z and therefore the mean velocity is proportional to the logarithm of the distance from the free surface (see references listed under further reading). Indeed this scaling can be found in the upper part of the OML, except close to the surface. Close to the surface, under strong wind conditions, modern measurements have found that the dissipation rate is one to two orders of magnitude larger than that given by the law of the wall (**Figure 3**). This near-surface elevated dissipation rate is due to the influence of surface waves and wave breaking. Wave breaking generates intermittent, shear-free turbulence somewhat akin to the turbulence generated by a stirring grid in a fluid. The turbulence intensity drops off sharply away from the source. Therefore, while the turbulence intensities are elevated above the usual levels during extensive wind-wave breaking, this turbulence is important only to a depth on the order of the amplitude of the breaking waves. Below these depths, the law of the wall can often be found once again. Wave breaking and associated turbulence are likely to be important for the dynamics of OMLs, especially shallow ones; because of the elevated near-surface dissipation rates, they may bring about a higher exchange of gas and heat across the air–sea interface. If it were not for the surface waves, the turbulence near the surface of an OML would behave roughly similar to that adjacent to a solid boundary, such as the ABL over land.

Solar Heating

The solar radiation incident on the ocean surface can be divided into three components: short wavelengths in the ultraviolet part of the spectrum ($<350 \text{ nm}$), the wavelengths available for photosynthesis (photosynthetically available radiation (PAR), $350\text{--}700 \text{ nm}$), and the infrared and near-infrared wavelengths ($>700 \text{ nm}$). The ultraviolet portion is roughly 2%, PAR 53%, and infrared 45% of the total solar insolation. PAR coincides roughly with the visible portion of

Figure 2 OML driven by freezing and salt extrusion underneath a refreezing lead. Top panel corresponds to stationary ice cover, when free convection dominates, and the bottom panel to the case when the ice is in motion, when forced convection dominates the mixing process.

the spectrum and is the most important of the three portions for biological aspects of the upper ocean. Primary productivity and fixing of carbon by phytoplankton take place only in the euphotic zone, defined as the depth at which respiration and primary production balance, which is where PAR decreases to 1% of its surface value. The ultraviolet part is important to the production of certain photochemicals such as carbonyl sulfide. **Figure 4** shows the spectrum of solar insolation at the top of the ocean and at various depths. Only the visible part remains below about 10 m.

Air–Sea Fluxes

For air–sea exchange purposes, fluxes of momentum, sensible and latent heats, water vapor, and dissolved gases such as CO_2 across the air–sea interface affect both the ABL and the OML. The transfer of momentum from winds to surface waves is usually relevant only in so far as it affects the net transfer to the ocean currents. However, the water vapor and gas fluxes from the oceans to the atmosphere, which are usually net losses to the ocean, are also important. All the fluxes of heat, mass, momentum, and gases are determined by turbulent

processes in the surface layers of the atmosphere and the ocean adjacent to the air–sea interface, with surface waves playing an important role by virtue of their ability to act as sinks of momentum, to determine the ‘roughness’ of the sea surface, and to disrupt the aqueous molecular sublayer responsible for transfer of scalar properties across the interface. At sufficiently high wind speeds, spray and droplets ejected into the atmosphere and air bubbles entrained into the ocean during wave breaking directly affect the fluxes between the two media.

There must be a balance among fluxes of all scalars, including heat, at the interface (**Figure 5**).

$$SW_{\downarrow} + LW_{\downarrow} + H_{pr} - SW_{\uparrow} - LW_{\uparrow} - H_s - H_L - SW_{\downarrow}^p = Q_{net} \quad [1]$$

where $SW_{\uparrow} = \alpha SW_{\downarrow}$; α is the albedo of the ocean surface. There is thus a balance between the downwelling shortwave ($SW_{\downarrow}$) and longwave ($LW_{\downarrow}$) radiative fluxes, and the upwelling $SW_{\uparrow}$ and $LW_{\uparrow}$ fluxes, the sensible (H_s) and latent (H_L) heat fluxes, the heat flux due to any precipitation (H_{pr}), the solar radiative flux penetrating into the ocean ($SW_{\downarrow}^p$) and the net heat flux Q_{net} at the surface. Treating the mixed layer as

Figure 3 Measured dissipation rate of TKE in the near-surface layers of the OML. The dissipation rate is more than an order of magnitude higher than that expected from the classical law of the wall scaling.

Figure 5 A sketch of the heat fluxes at the air-sea interface.

a slab, the rate of change in temperature of the OML due to the effects of the surface fluxes is given by the upper ocean heat budget:

$$\frac{\partial T}{\partial t} = \frac{Q_{\text{net}}}{\rho C_p D} + (U_{\text{geo}} + U_{\text{Ek}}) \cdot \nabla T + \frac{(W_e + W_{\text{Ek}})(T - T_b)}{D} + \kappa \nabla^2 T \quad [2]$$

where T is the OML temperature, D its thickness, ρ and C_p are the density and specific heat of air, U_{geo} and U_{Ek} are the geostrophic and Ekman currents, W_e is the entrainment velocity associated with a deepening of the mixed layer, W_{Ek} is the Ekman current velocity, T_b is the temperature below the mixed layer, and κ is the diffusivity of temperature. These terms thus describe the temperature change due to surface heat flux, advection, entrainment, and diffusion.

The net salinity flux to the ocean is

$$F_S = (\dot{P}_{\text{r,sn}} - \dot{E})(-S_s); \quad \dot{E} = H_L/L_E \quad [3]$$

where $\dot{P}_{\text{r,sn}}$ is the precipitation (rain or snow) rate (m s^{-1}), $\dot{E}$ is the evaporation rate, S_s is the surface salinity, and L_E is the

Figure 4 Solar insolation at the ocean surface and below. Note the rapid attenuation of nonvisible components with depth. Only the visible part remains below about 10 m depth.

latent heat of evaporation. Precipitation tends to suppress mixing because of the stabilizing effect of fresh water precipitated onto the salty water of the ocean. The net buoyancy flux due to precipitation is normally stabilizing, since the salinity effect overwhelms any thermal effect. As with temperature, the rate of change of salinity in the OML can be written as:

$$\frac{\partial S}{\partial t} = \frac{(\dot{E} - \dot{P})S}{D} + (U_{\text{geo}} + U_{\text{Ek}}) \cdot \nabla S + \frac{(W_e + W_{\text{Ek}})(S - S_b)}{D} + \kappa \nabla^2 S \quad [4]$$

with the salinity changing as a result of the net surface fresh-water flux, advection, entrainment, and diffusion. Subscripts and symbols are as with the temperature equation.

Momentum is a conserved quantity. Therefore, the momentum flux must also be in balance at the air-sea interface. This just means continuity of stresses at the interface, in particular, tangential stresses,

$$\tau_a + \tau_{\text{pr}} = \tau_w + \tau_{\text{wv}} \quad [5]$$

where τ_a is the air-side stress (the shear stress applied by the atmosphere to the ocean), τ_w is the water-side stress (negative of the drag exerted by the ocean on the atmosphere), τ_{wv} is the momentum flux radiated out by propagating surface waves generated by the wind, and τ_{pr} is the momentum flux due to any precipitation, approximately equal to $\rho_w \dot{P} U_{10}$, where ρ_w is the density of water and U_{10} is the air velocity at anemometric height (10 m). Enormous effort has gone into parameterizing τ_a in terms of the atmospheric variables and τ_{wv} , since they determine the value of τ_w . The momentum flux to the surface waves is a drag exerted on the atmosphere and is therefore important. It is especially important in the initial stages of development of the wave field (meaning short fetches or immediately following a change in the wind), since a considerable fraction of the momentum flux from the atmosphere goes then into generating the waves, with the remainder going directly into ocean currents. For a mature wave field, however, near-equilibrium conditions prevail and most of the momentum flux put into waves is immediately 'lost' and transferred to the currents, and τ_{wv} can be safely neglected. It is difficult in practice to compute τ_{wv} without a wave model, and it is a normal practice to ignore τ_{wv} and put $\tau_w = \tau_a$ in the absence of any precipitation.

Sensible and latent heat fluxes, as well as long wave back radiation at the ocean surface occurs across the skin of the ocean. Within this skin layer, which is on the order of a millimeter in thickness, there is usually a sharp drop in temperature of a few tenths of a degree Celsius (Figure 6). Exchanges of heat, momentum, and mass through this region are by molecular processes. This cool skin plays an important role in air-sea transfer processes, because of its influence on air-sea temperature and humidity differences. Transport of dissolved gases also occurs across a molecular sublayer of similar thickness to the thermal sublayer as do the transports of momentum and mass. Below this thin layer, turbulent processes dominate, driven by momentum and energy exchanges from the atmosphere to the ocean. The presence of the wave sublayer and a mobile interface, whose roughness as felt by both the ocean and the atmosphere is dynamically determined, provides the most important distinction between an ABL over land and that

Figure 6 A sketch of the air-sea interface showing the molecular sublayers on the air and the water sides. The heat flux through sublayer

over the ocean. Consequently, surface layer similarity laws derived from the ABL over land are imprecise analogies when applied to the ABL over water and the OML. For the OML, the fraction of the OML affected directly by wave orbital velocities and hence wave dynamics can be large.

However, the wave generated currents and turbulence in the upper ocean do not just simply coexist. Recent advances in wave-turbulence interactions indicate that transfer of energy to turbulence from waves occurs even without wave breaking. The mechanism is the so-called Stokes production of TKE. The Stokes drift current (a small steady Lagrangian residual current in the direction of surface wave propagation which decays exponentially with depth) produced by wind waves augments the mean current produced by the wind stress acting at the surface. The Reynolds stresses acting on the vertical shear of the Stokes drift in the water column extract energy from waves and transfer it to turbulence, in exactly the same manner in which Reynolds stresses extract energy from the mean currents through interaction with the mean shear. The salient parameter is the modified Langmuir number (introduced by Kantha)

$$\text{La}_K = \left[\frac{(\vec{\tau}_w / \rho_w) \cdot (\vec{U}_S)}{u_*^3} \right]^{1/3} = \left(\frac{|\vec{U}_S| \cos \theta}{u_*} \right)^{1/3} \quad [6]$$

where $\vec{U}_S$ is the Stokes drift velocity at the surface and θ the angle between wind stress and the direction of wave propagation. The larger this number, the higher the Stokes production of TKE. Stokes production constitutes an important source of turbulent mixing in the upper ocean (Figure 7) and is now being incorporated into ocean models. This mechanism is also of importance to wind-generated waves over the ocean, since it constitutes an important sink mechanism for surface gravity waves in the presence of turbulence in the OML. The Stokes dissipation rate of wind wave energy in the ocean is more than 2.5 terawatts on the average, which is more than the dissipation rate of wind wave energy in all the surf zones around the ocean margins.

Langmuir Cells

Langmuir cells are organized counter-rotating cells in the surface layer (Figure 8), with axes roughly aligned with the wind. Their

Figure 7 Shear production of TKE (top two panels) and Stokes production of TKE (bottom panel) shown in logarithmic scale (in units of $\text{m}^2 \text{s}^{-3}$) for a station in the Baltic Sea. The top panel is for the case without wave breaking or Stokes production. Middle panel shows including them produces some minor changes in shear production. The bottom panel shows that Stokes production is comparable in magnitude to shear production and hence is important to include in OML models. Reproduced from Kantha, L., Lass, H.U., Prandke, H., 2010. A note on Stokes production of turbulence kinetic energy in the oceanic mixed layer: observations in the Baltic Sea. *Ocean Dynamics*, 60, 171–180.

presence is indicated by surface convergence at the boundary of counter-rotating cells, where seaweed and flotsam accumulate. The convergence region is also made visible by white-capping and bubble entrainment due to breaking of small scale waves

Figure 8 Langmuir cells and the associated velocities. Note the 'wind-rows' and the strong near-surface vertical velocities associated with the convergence zones of a pair of counter-rotating cells.

resulting in parallel white lines roughly aligned with the wind and roughly uniformly spaced. Bubble clouds in water are also concentrated at surface convergence zones and are visible in side-scan sonar observations.

Organized motions in the OML such as those due to large eddies and Langmuir circulations are important to upper ocean mixing and transport. Langmuir cells can be quite vigorous with downward vertical velocity immediately below the convergence zone as high as a few tens of cm s^{-1} . These motions are capable of not only injecting additional energy into the OML for mixing, but also transporting particles such as phytoplankton deep into the OML. They are however transient processes and are not easily quantified. Their existence depends on the presence of a surface wave field with the associated Stokes drift. An instability brought on by the vortex force term that appears in the momentum equations due to the interaction of the Stokes drift with the mean shear in the upper layers leads to the formation of Langmuir cells. Thus they are unique to the oceans since they result from a subtle interaction of the wind-driven turbulence and the Stokes current drift produced by surface gravity waves. Observational programs and advanced computer models such as large eddy simulations are helping us understand such large-scale features of the OML. Langmuir cells can have a dramatic effect on shallow diurnal mixed layers and can wipe out the strong diurnal peaks in the SST that would otherwise be manifest when solar insolation is strong and winds are weak. Their effect on mixing in deep

mixed layers can also be significant, even though the Stokes drift decays rapidly with depth.

The characteristic velocity scale for Langmuir circulation is,

$$V_L = [(\vec{\tau}_w / \rho_w) \cdot (\vec{U}_S)]^{1/3} \quad [7]$$

$$\text{For monochromatic waves, } V_L = [u_*^2 (ka)^2 C \cos \theta]^{1/3} \quad [8]$$

where u_* is the friction velocity, k is the wavenumber, C the phase speed, and a the amplitude of the surface waves. Note that $La_K = \frac{V_L}{u_*}$. Clearly, the strength of the Langmuir cells depends on both the Stokes drift and wind stress, so that strong winds and small waves can have an influence similar to that of weak winds and large waves.

Deep Convection

There exist a few regions in the high latitude oceans where convection is both deep and long lasting. Under the present climatic conditions, in the Greenland Sea, the Labrador Sea, and the western Mediterranean Sea in the northern hemisphere, and in the Weddell Sea in the southern hemisphere, strong, prolonged wintertime cooling occurs at the surface, leading to deep convective layers that extend over most of the water column. More recently, deep convection has been shown to occur along oceanic fronts, particularly in the Japan (East) Sea. Deep convection in the open ocean is the means by which the deep ocean is ventilated and its thermal structure maintained. The resulting meridional thermohaline circulation, and the poleward oceanic heat transport from the low latitudes to the midhigh latitudes associated with it, has a major influence on the climate at these latitudes. In these few deep convection regions, the stable stratification in the water column that normally isolates the abyss from the atmosphere is broken down violently by strong convective cooling at the surface. The associated timescales are much larger than the inertial period ($2\pi/f$, where $f = 2\Omega \sin \varphi$ is the Coriolis parameter, Ω being the angular velocity of Earth, and φ being the latitude) and hence deep convection occurs under the influence of Earth's rotation.

There are three phases of the most common form of deep convection: (1) The preconditioning phase, where the prevailing large-scale circulation brings the weakly stratified deep water masses closer to the surface for the stratification to be gradually eroded by strong sustained surface cooling during early winter. This phase is crucial to the whole process. Deep convection in the open ocean unassociated with oceanic fronts is found only in regions with cyclonic circulation that causes an upward doming of the isotherms. In the Labrador Sea, the cyclonic circulation is due to the West Greenland and Labrador Currents hugging the continental slope. In the Mediterranean, the cyclonic Lions Gyre provides the preconditioning. Strong, sustained cooling is also essential to breakdown the stratification built up in the upper layers during the previous spring and summer. It is interesting that even stronger heat losses ($\sim 1000 \text{ W m}^{-2}$) occur in the oceans during wintertime cold air outbreaks off the east coasts of continents leading to strong cyclogenesis in the atmosphere, but not deep-water formation because of the brevity of the events. In the polar oceans, the air-sea temperature differences during off-ice wind conditions

can reach 30–40 °C, and if sustained long enough can lead to intermediate and deep dense water formation, examples being the Weddell Sea in the Antarctic, the Sea of Okhotsk, and the Arctic shelves. (2) Eventually the stratification breaks down. A strong cooling event lasting several days with heat losses of 500–1000 W m^{-2} , brought on by air-sea temperature differences of 8–12 °C, and strong wind bursts are common. Deep convection ensues with intense plumes a few kilometers in size reaching down to as deep as 2–3 km. (3) The cooling weakens, and the well-mixed water mass in the convective 'chimney' spreads laterally, undergoing baroclinic instabilities in the process, and mixes with the ambient waters. Stratification is restored and the stage is set for the next cycle.

The most relevant parameters in deep convection are the buoyancy flux (due to both sensible and evaporative heat losses) B_0 that can reach values of $1\text{--}3 \times 10^{-7} \text{ m}^2 \text{ s}^{-3}$, the inertial frequency f , the depth of the mixed layer D , 1000–3000 m, and the Rossby radius of deformation $a = \frac{c}{f}$

(where c is the internal gravity wave speed), typically a few kilometers. Rossby radius is indicative of the horizontal scales of motion under the influence of ambient rotation. Under conditions where the rotational effects dominate, the

relevant length and velocity scales are $l_{dc} = \left(\frac{B_0}{f^3}\right)^{1/2}$ and

$$u_{dc} = \left(\frac{B_0}{f}\right)^{1/2}. \text{ The associated Rossby number } Ro = \frac{u_{dc}}{l_{dc}f},$$

characterizing the relative importance of rotation, is unity. The relevant Rayleigh number, a parameter of importance

in thermal instability and free convection, $Ra = \frac{B_0 D^4}{\nu k^2}$,

is very large on the order of 10^{26} . Note that in the atmosphere, where rotational effects are not important, the relevant length scale is D_{ABL} , the thickness of the ABL and the relevant velocity scale is the Deardorff velocity scale $w_* = (B_0 D_{ABL})^{1/3}$, indicative of the typical velocities in a convective ABL.

Numerical Models

OML models can be grouped into roughly two categories: bulk (or slab) models and diffusion models. Bulk models attempt to model the OML in an integral sense. The governing equations are integrated over the mixed layer so that the momentum and heat balance of the entire mixed layer, under the action of momentum and buoyancy fluxes at the ocean surface, can be considered. The major problem in bulk mixed layer modeling arises from the necessity to parameterize the advance and retreat of the OML under the action of surface momentum and buoyancy fluxes. The deepening of the OML is due to the entrainment rate at the base of the OML, which is determined by turbulence processes. The entrainment rate has been a subject of both laboratory and field experiments. It is also necessary to know the depth to which turbulence generated at the surface can penetrate under the action of a stabilizing buoyancy flux at the surface (as for example, during a rainstorm or strong solar heating), in order to determine the OML depth under these conditions. Bulk models parameterize the entrainment (OML deepening) and

Figure 9 Comparison of (a) observed and (b) one-dimensional mixed layer model-simulated mixed layer temperatures at Ocean Station PAPA in the North-Eastern Pacific. Simulations are remarkably good given the large uncertainties associated with forcing parameters and the neglect of advection effects.

‘detrainment’ (OML retreat) in terms of surface fluxes of momentum and buoyancy, using the well-known properties of turbulence in geophysical mixed layers and/or observational evidence. The K-profile parameterization (KPP) model is a good example. It was built originally by borrowing ideas from the ABL over land and has been routinely included in ocean models used for long-term simulations. The surface wave effects were however absent in the original formulation.

Diffusion models parameterize turbulent mixing in the OML. Those based on higher moments of governing equations close the governing equations for turbulence quantities at some level by judicious modeling of the unknown higher moments and other terms. Once turbulence is thus quantified, it is a straightforward matter to deduce the mixing intensity. In second-moment closure models, the turbulence equations are closed at the second-moment level; conservation equations for turbulence Reynolds stresses, heat fluxes, and scalar variances are solved by modeling the unknown third-moment turbulence quantities and pressure-strain rate and pressure-scalar gradient covariance terms by appealing to physical intuition and/or observational evidence (and lately to Large Eddy Simulations of turbulence). However, the complexity of this approach is at least an order of magnitude more than that of the simpler models cited above, since there is now a need to solve partial differential equations governing second moments in addition to the usual ones for mass, momentum (for U and V), and scalar (for T and S) conservation. Attempts have therefore been made to simplify the set by once again utilizing certain aspects of

turbulence such as its departure from the state of local isotropy. The result is a hierarchy of models, of which the most useful for geophysical applications is the model that consists of one conservation equation for TKE (half the square of the turbulence velocity macroscale q), and a set of algebraic equations for turbulence second-moment quantities. The resulting simplicity and the potential ‘universality’ of application are of particular interest in modeling OMLs. Since the most basic description of turbulence is incomplete without quantifying its macro length scale l , this set is supplemented either by auxiliary information on the turbulence length scale, or by utilizing an equation for a quantity that includes the turbulence length scale such as dissipation rate (q^3/l) or the product of the turbulence length scale and twice the TKE ($q^2 l$). **Figure 9** shows an example of the accuracy attainable with a current generation OML model. For the current state of OML modeling using second moment closure, see the 2011 review article by L. Kantha, listed in the references. See also the book *Marine Turbulence*.

To summarize, there has been a significant improvement in our understanding of the OML in the last decade since the first publication of this Encyclopedia. However, much work remains and any further improvement in understanding and quantification of the state of the OML requires a concerted and combined observational, theoretical, and modeling effort to address the holes in our knowledge. While significant progress has been made in modeling the OML under strong stable stratification, modeling mixing under convective or near-convective conditions, where counter-gradient transport by large eddies is important, is still imprecise.

Stably Stratified Boundary Layer

L Mahrt, Oregon State University, Corvallis, OR, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The traditional formulation of the stable boundary layer is briefly reviewed including the vertical structure, similarity theory, and stability parameters. A number of complications are considered including very stable conditions where the primary source of the weak turbulence may be detached from the surface, sometimes related to the nocturnal jet. The role of a vegetation canopy and surface heterogeneity are considered. Nonstationarity and meandering of the wind vector for very stable weak wind conditions are discussed.

Introduction

Stable boundary layers are most commonly generated by surface radiative cooling or advection of warm air over a cooler surface. Turbulence transports heat toward the cooler surface. The actual transfer of heat to the surface occurs by thermal conductivity through a thin laminar sublayer, perhaps only a few millimeters thick. However, the rate of this heat conduction is dictated by the downward turbulent transport of heat to the laminar sublayer. Therefore, we concentrate on the turbulent transfer.

The downward transport of heat corresponds to downward buoyancy flux that destroys turbulent kinetic energy. That is, the energy required to push warm, light air downward and lift cold heavy air upward comes at the expense of the turbulence kinetic energy (conversion of turbulence kinetic energy to potential energy). Therefore, for a given wind speed and surface roughness, the turbulence is weaker with downward buoyancy flux compared to the case of no buoyancy flux or upward buoyancy flux. In general, the buoyancy flux is downward when the boundary layer is stably stratified; that is, when the potential temperature increases with height. To simplify the discussion of a very complex subject, we make an idealized distinction between cases where such buoyancy effects are weak or strong and then move on to consider general aspects of the stable boundary layer, which apply to a wide range of stabilities.

Basics

Turbulent fluctuations of a generic variable ϕ are mathematically defined as deviations from a mean value as in eqn [1].

$$\phi' \equiv \phi - \bar{\phi} \quad [1]$$

The overbar defines a time-, space-, or volume-average. ϕ may be potential temperature, one of the three velocity components, or concentrations of gases such as water vapor or carbon dioxide.

We proceed with time averaging of the flow at a fixed point in space. The turbulent vertical flux of quantity ϕ is then computed as expression [2].

$$\overline{w'\phi'} \quad [2]$$

The vertical flux may then be averaged over a longer averaging time to reduce random flux errors. The vertical divergence of the vertical flux appears in the budget equation for ϕ , such as the equations of motion for momentum, provided that the averaging process defined by the overbar satisfies Reynolds averaging. This requirement is satisfied by simple unweighted averaging. With filtering or a moving average, additional flux terms result in the budget equations. This topic is beyond the scope of this article.

Fluxes in the stable boundary layer are often formulated in terms of local vertical gradients through use of an eddy diffusivity as in eqn [3], where K_ϕ is the eddy diffusivity for vertical transfer of variable ϕ .

$$\overline{w'\phi'} = -K_\phi \frac{\partial \bar{\phi}}{\partial z} \quad [3]$$

Such a formulation is likely to be useful in the stable boundary layer where the eddies are locally generated by shear and are of small vertical scale. In contrast, the eddy diffusivity is not likely to be useful in the convective daytime boundary layer where large eddies transport according to a vertical gradient over the depth of the entire boundary layer (see **Thermodynamics: Moist (Unsaturated) Air**).

The eddy diffusivity is often related to a form of the Richardson number. The flux Richardson number is defined in eqn [4], where $\bar{\theta}_v$ is the averaged virtual potential temperature.

$$Rf \equiv - \frac{(g/\bar{\theta}_v) \overline{w'\theta'_v}}{\overline{w'u'}(\partial \bar{u}/\partial z) + \overline{w'v'}(\partial \bar{v}/\partial z)} \quad [4]$$

Often, the influence of moisture fluctuations on the buoyancy are neglected so that θ_v is replaced by θ . The numerator of Rf is the buoyancy-destruction or generation of the turbulence kinetic energy, while the denominator is the shear-generation of turbulence. The following considers positive Richardson numbers where the turbulence is destroyed by buoyancy effects, which can also serve as a definition of the stable boundary layer.

Approximating the fluxes in terms of an eddy diffusivity and rotating the x -coordinate into the direction of the mean vertical shear, the flux Richardson number becomes as shown in eqn [5], where K_m and K_h are the eddy diffusivities for momentum and heat, respectively.

$$Rf = \frac{(g/\bar{\theta}_v) K_h \partial \bar{\theta}_v / \partial z}{K_m (\partial \bar{u} / \partial z)^2} \quad [5]$$

The flux Richardson number then becomes Ri/Pr , where Pr is the eddy Prandtl number, defined as k_m/k_h , and Ri is the gradient Richardson number defined by eqn [6].

$$Ri = \frac{(g/\bar{\theta}_v)\partial\bar{\theta}_v/\partial z}{(\partial\bar{u}/\partial z)^2} \quad [6]$$

In numerical models and with observations, the gradients are approximated with finite differencing between different discrete vertical levels, designated by the δ operator, which leads to the layer Richardson number Ri_L given by eqn [7].

$$Ri_L = \frac{(g/\bar{\theta}_v)\delta\bar{\theta}_v\delta z}{(\delta\bar{u})^2 + (\delta\bar{v})^2} \quad [7]$$

A bulk Richardson number for the entire boundary layer is formed by choosing the two levels to be the surface and the top of the boundary layer; that is, replacing δz in eqn [7] with the boundary layer depth and replacing $\delta\bar{u}$ and $\delta\bar{v}$ with the wind components at the boundary layer top.

In some studies, the turbulence is considered to be first generated when the layer Richardson number decreases to 0.25, referred to as the critical Richardson number. This expectation is based on linear instability theory in terms of the gradient Richardson number. However, turbulence has been observed at much larger values of the layer Richardson number. This could be due in part to nonstationarity where the turbulence decays over a finite period after the layer Richardson increases above the critical value. However, the critical value of the layer Richardson number may increase with the distance between the vertical levels, δz . Apparently, turbulence may occur in sublayers smaller than δz even if the layer Richardson number is large.

The eddy diffusivity, K_ϕ , is sometimes formulated in terms of a Richardson number. Some formulations specify the eddy diffusivities to vanish at the critical Richardson number, while other formulations, recognizing the above complexities, specify the eddy diffusivity to gradually decrease with increasing Richardson number. The eddy Prandtl number K_m/K_h increases with the Richardson number, apparently owing to some momentum transfer by gravity waves.

If the eddy diffusivity represents the vertical turbulent flux over a horizontal area, the concept of a critical Richardson number is not applicable. No matter how large the Richardson number becomes, based on spatially averaged variables, some intermittent turbulence may occur somewhere within the area. Such a horizontal area might correspond to a grid area in a numerical model.

Weak Stability

With weak buoyancy effects, the boundary layer turbulence is generally continuous in time and space. The strength of the turbulence decreases with height and vanishes at the top of the boundary layer. These conditions often occur during the night with significant wind speed or cloudy conditions. The more stable case, corresponding to clear skies and weak winds, is discussed in the next section. Three idealized layers can be defined in the weakly stable boundary layer (Figure 1).

Figure 1 Idealized layering of the stable boundary layer. With strong stability, the vertical structure is less organized. The numerical values of the heights above ground are just examples. For example, the boundary-layer depth may be as small as a few meters or larger than 500 m.

Roughness Sublayer

In the roughness sublayer close to the plant canopy, the time-averaged flow varies spatially on the scale of the plant elements and a universal flux–gradient relationship seems unobtainable. For example, the flux immediately above a plant will be different from the flux at the same level between plants. Although the roughness sublayer has been studied in some detail, the generality of such studies is unknown.

Surface Layer

Above the roughness sublayer, in the surface layer (Figure 1), the individual plant elements no longer induce small-scale horizontal variation of the time-averaged flow. Then, the height above ground and the Obukhov length (defined below) are the only relevant length scales, in which case Monin–Obukhov similarity theory is valid. This theory requires that the flow is stationary and homogeneous and that $z \ll h$ where h is the boundary layer depth and z is the height above ground. Sometimes, the surface layer is assumed to extend upward to about 10% of the boundary layer depth. This condition on depth allows neglect of the height variation of the fluxes in the surface layer.

The Obukhov length is defined as in eqn [8], where κ is the von Karman constant and g is the acceleration of gravity, $(w'\theta'_v)$ the kinematic virtual heat flux (buoyancy flux) in the surface layer, assumed to be a good approximation to the surface flux, and u_* is the surface friction velocity, defined in eqn [9].

$$L \equiv -\frac{\bar{\theta}_v u_*^3}{kgw'\theta'_v} \quad [8]$$

$$u_* \equiv \left(\overline{w'u'^2} + \overline{w'v'^2} \right)^{1/4} \quad [9]$$

In eqn [9] $\overline{w'u'}$ and $\overline{w'v'}$ are the components of the momentum flux in the surface layer, also assumed to be good

approximations to the surface momentum flux. The Obukhov length represents the relative importance of mechanically generated turbulence (shear-generated turbulence associated with the roughness of the surface) to the buoyancy-destruction (or generation) of turbulence. The ratio z/L is the stability parameter, which ranges from zero at neutral conditions (no virtual heat flux) to values on the order of one and greater for very stable conditions.

The surface stress can be related to the wind speed, V , with the bulk formula, written as in eqn [10], where C_D is the drag coefficient.

$$u_*^2 = C_D V^2 \quad [10]$$

The drag coefficient is formulated in terms of Monin-Obukhov similarity theory as in eqn [11].

$$C_D = \left[\frac{k}{\ln(z/z_{om}) - \psi(z/L)} \right]^2 \quad [11]$$

The parameter κ is the von Karman constant, typically taken to be about 0.4. The stability function ψ is specified to be a function of z/L , based on parametrizations available in the suggested Further Reading at the end of the article. For stable conditions, the value of ψ is negative, associated with reduction of turbulent mixing by stratification. Thus, the drag coefficient is small compared to the case of no virtual heat flux ($\psi(z/L) = 0$). The roughness length for momentum z_{om} represents the influence of the surface on the momentum flux-gradient relationship in the surface layer. Generally, a rougher surface corresponds to a larger surface roughness length, which in turn leads to greater turbulence. Corresponding relationships for the transfer coefficients for surface fluxes of heat, moisture, and other scalar quantities are defined in terms of scalar roughness lengths. Over vegetated surfaces, scalar roughness lengths are not as well behaved as that for momentum. The stability functions for scalars can be found in the Further Reading. These references also include completely different similarity theories for prediction of the drag coefficient and transfer coefficients, which are defined in terms of the geostrophic wind.

When evaluating similarity theory from actual data, one must assess the importance of artificial self-correlation. For example, C_D is correlated with ψ even if the fluxes are randomly generated variables. This is because both C_D and ψ are functions of the surface friction velocity u_* . This self-correlation can be eliminated by replacing the stability parameter z/L with the surface bulk Richardson number Ri_b given by eqn [12], which is a form of eqn [7].

$$Ri_b \equiv \frac{(g/\theta_v)(\theta_v(z) - \theta_v(sf))z}{(V(z))^2} \quad [12]$$

Here, $\theta_v(sf)$ is the surface virtual potential temperature, corresponding to the ground surface temperature (often the surface radiation temperature), and $V(z)$ is the wind speed at level z , which is within the surface layer.

Boundary Layer Interior

Above the surface layer, the approximation of height-independent fluxes is no longer valid. The fluxes normally decrease with height and reach small values at the top of the

boundary layer. However, if the Obukhov length is redefined in terms of local fluxes, similarity theory can be restored in the form of local scaling in which z/L is replaced by z/Λ , where Λ is the Obukhov length based on the local fluxes at height z . The length scale Λ reduces to the Obukhov length when z is in the surface layer.

The vertical structure above the surface layer is often expressed as functions of z/h , where h is the boundary layer depth. For example, the eddy diffusivity is sometimes modeled as a function of z/h . The classical Ekman solution is a special case corresponding to a balance between the vertical divergence of the momentum flux, the horizontal pressure gradient, and the Coriolis force. The simplest form of the Ekman solution assumes a height-independent eddy diffusivity.

Boundary Layer Top

Sometimes the top of the stable boundary layer is viewed as an entrainment layer where turbulent eddies engulf air from above the boundary layer and mix it downward. This concept applies with growing stable boundary layers, usually corresponding to windy conditions. During fair weather conditions, the air above the nocturnal boundary layer would have been within the deeper convective boundary layer in the daytime. This layer above the nocturnal boundary layer is referred to as the 'residual layer' (Figure 1). This layer 'remembers' the daytime convective layer in that the stratification usually remains weak. As a result, modest vertical shear generates turbulence in the residual layer.

The depth of the stable boundary layer is sometimes modeled by assuming that the bulk Richardson number for the boundary layer is equal to a critical value or constantly adjusts toward the critical value. Other formulations express the boundary layer depth in terms of length scales such as u_*/f , where f is the Coriolis parameter. The later formulation does not apply at low latitudes.

Strong Stability

The very stable boundary layer occurs with clear nocturnal skies and weak winds or with advection of warm air over a much cooler surface. The very stable boundary layer is of considerable practical importance. The absence of significant mixing allows buildup of high concentrations of contaminants near the surface. Frost damage is most likely to occur in the very stable case where the downward turbulent heat flux from above is suppressed (Figure 2), leading to even greater surface cooling.

With strong buoyancy effects, the turbulence is more likely to be intermittent, with brief episodes of turbulence separated by intervening periods of relatively weak or unmeasurably small fluctuations. The term intermittency is somewhat ambiguous in that all turbulence is considered to be intermittent to the degree that the fine scale structure occurs intermittently within larger eddies. This intermittency within a given large eddy is referred to as fine scale intermittency.

Global intermittency defines the case where eddies on all scales are missing or suppressed on a scale that is large compared to the large eddies. Global intermittency is sometimes viewed as a sequence of events beginning with reduction

Figure 2 Typical variation of the eddy diffusivity and the virtual heat flux with stability, z/L , or Ri_b .

of the mean shear by mixing and the corresponding increase of the Richardson number to values greater than the critical value. This stage is followed by collapse of the turbulence. Without vertical mixing, the mean shear rebuilds such that the Richardson number falls below the critical value and turbulence is regenerated. With this interplay between the turbulence and mean shear, the Richardson number stays close to the critical value.

Additional characteristics of the very stable case may include significant gravity wave transport, layering of turbulence, and the absence of a well-defined boundary layer top. The boundary layer may assume an upside-down form, where the principal turbulence is detached from the surface. This detachment may be only temporary since decoupling with the surface leads to flow acceleration above the stable layer adjacent to the surface. The resulting development of shear generates turbulence and recoupling with the surface (Figure 3). Thus, the concept of an upside-down boundary layer, top-down transport of turbulence kinetic energy toward the surface and cyclic behavior about a critical value of the bulk Richardson number may all be related.

Figure 3 Hypothetical schematic of one type of diurnal variation of the nocturnal boundary layer. Shaded regions indicate significant turbulence.

However, a unified picture or theory of the very stable case does not exist owing to both the difficulty of measuring weak intermittent turbulence with existing instrumentation and the complex multitude of different physical processes with strong stability.

Very Stable Surface Layer

The turbulence and eddy diffusivity near the surface are sometimes observed to decrease rapidly as z/L exceeds a critical value, as qualitatively sketched in Figure 2. This rapid decrease marks the beginning of the very stable regime. Unfortunately, the critical value of z/L varies between observational studies. The downward heat flux seems to reach a maximum value at the beginning of the transition between the weakly and very stable cases. With stronger stability, the vertical velocity fluctuations are suppressed, which reduces the downward heat flux. For weaker stability, the temperature fluctuations are small as a result of small vertical gradients of potential temperature. The downward buoyancy flux vanishes as the vertical gradients of potential temperature vanish (neutral stability).

Virtually all models apply Monin–Obukhov similarity theory to the first model level above the surface to estimate surface fluxes, even for very stable conditions where Monin–Obukhov similarity may apply only to levels below the first model level, or may not apply at all. No other practical formulations exist.

The turbulence in the very stable surface layer may be intermittent, sometimes related to downward bursts from turbulence generated aloft. Clear air radiative flux divergence, transport by nonlinear gravity waves, drainage flows, and surface heterogeneity (see later) may invalidate assumptions required for Monin–Obukhov similarity theory.

Interior of the Boundary Layer

Above the surface layer in very stable conditions, the eddies may no longer ‘feel’ the influence of the ground and the height above ground is no longer a relevant variable. This is referred to as ‘ z -less’ stratification. This flow cannot be modeled in terms of dependences on z/h since z is not a relevant variable and the boundary layer depth may not be definable.

Upside-Down Structure

Some very stable boundary layers take the appearance of an ‘upside-down’ boundary layer where the main source of turbulence is elevated and detached from the surface. In one scenario, turbulence adjacent to the surface collapses in the early evening, while some decaying turbulence remains at higher levels for a finite period of time (Figure 3). Flow above the surface inversion layer is now decoupled from the surface stress and accelerates, often leading to a low-level jet. The associated shear may induce turbulence above the surface inversion layer, which bursts downward toward the surface (Figure 3). Downward bursting of turbulence is one cause of intermittent turbulence at the surface.

With the upside-down structure, the usual concept of a boundary layer breaks down. We retain the term ‘boundary layer’ because the turbulence may be intermittently coupled to

the surface. In addition, the detached turbulence is often generated by shear associated with drainage flows, low-level jets, and gravity waves that are induced by surface processes. The detached turbulence may also be associated with the residual layer above the surface inversion, which in the early evening is characterized by decaying turbulence from the daytime boundary layer.

Similar behavior may occur with the advection of warm air over a much colder surface. For example, in advection of warm daytime air from land over colder water, the cooling of the air in contact with the water surface leads to strong stratification and suppression of the turbulence near the surface.

Low-Level Jet and Elevated Turbulence

Shear-generation of turbulence at the top of the surface inversion layer sometimes results from the formation of a low-level nocturnal jet. A nocturnal maximum in the wind profile can be generated by cooling over sloped terrain or inertial effects, described below.

Cooling over sloping terrain leads to a time-dependent, height-dependent horizontal pressure gradient force, which generates low-level flow. Small-scale sloping terrain leads to nonhydrostatic downslope drainage flows, which can be significant even over weak slopes if skies are clear and the large-scale flow is weak. On larger scales, the pressure field is hydrostatic. On still larger scale slopes, the flow becomes influenced by the Coriolis parameter.

As the second mechanism, nocturnal low-level jets are driven by ageostrophic flow caused by daytime frictional effects in concert with collapse of the daytime boundary layer in late afternoon. The turbulence and stress divergence vanish above the new thin nocturnal boundary layer, leading to an imbalance between the Coriolis and horizontal pressure gradient terms. This in turn induces an inertial oscillation. Spatial variations of the inertial oscillation generate vertical motions and adjustment of the pressure field, which feeds back upon the inertial oscillation.

Mesoscale Variations

Nocturnal mesoscale motions include cold air drainage and meandering motions, which might propagate from outside the local domain. Meandering motions refers to the ‘flopping around’ of the wind vector, most obvious with weak nocturnal airflow. Although meandering has been attributed to a variety of physical mechanisms, its link to these mechanisms has not been established from observations. It is not clear whether such motions systematically degrade Monin–Obukhov similarity theory. These mesoscale motions become relatively more important for the very stable case, partly because the turbulence is weaker.

Mesoscale motions may be locally generated in stably stratified flows by turbulence that decays into mainly horizontal motions, sometimes referred to as one type of meandering motion. Vortex motions in the horizontal plane (vertical vorticity) may merge into larger vortices, corresponding to upscale energy transfer. These theoretical

expectations have been difficult to verify with actual atmospheric data. Such meandering can be augmented by topography. These layered motions randomly enhance the shear between layers, which in turn intermittently regenerates local turbulence.

Vegetation Canopy

Most land surfaces are covered with some type of vegetation canopy, which substantially impacts the structure of the nocturnal boundary layer near the surface. The vegetation causes microscale variability on the scale of individual plants, leading to the roughness sublayer. With a partially open canopy, the subcanopy air is significantly stratified at night, partly owing to direct radiative cooling of the ground surface between the trees (Figure 4(a)). The net radiative cooling under each tree is small owing to downward longwave radiation emitted by the tree. With a closed canopy, the subcanopy flow may be stably stratified in the daytime and less stratified at night when the inversion is concentrated in the upper part of the canopy (Figure 4(b)). Some of the air cooled at the canopy top sinks into the subcanopy, leading to vertical mixing of the subcanopy flow.

Irregularity of the canopy top due to individual trees may induce gravity waves in the nocturnal boundary layer.

Enhanced Influence of Surface Heterogeneity

Since vertical mixing in the very stable boundary layer is due to weak small eddies, small-scale heterogeneity may become important even though the influence of the same surface heterogeneity in the daytime, convectively heated, boundary layers is eliminated by large convective eddies. Such small-scale heterogeneity might include clumps of trees or bushes, isolated buildings, or horizontal variation of heat flux from the soil due to variations of soil type and moisture on

Figure 4 The nocturnal boundary layer for (a) an open canopy and (b) a closed canopy. R_{net} is the net radiation. The potential temperature profile is indicated on the left.

horizontal scales as small as tens of meters. The nocturnal boundary layer is slow to adjust and is therefore easily influenced by surface heterogeneity. On the other hand, mesoscale surface heterogeneity over flat surfaces with stable stratification is less likely to generate its own secondary circulation since stationary vertical motion fields are inhibited by the stratification through hydrostatic pressure adjustments. For example, rising motion induced by a relatively warm surface area generates adiabatic cooling in the stratified atmosphere, which acts to increase the surface pressure, which in turn opposes the horizontal inflow.

Synopsis

The atmospheric surface layer represents the medium for nearly all activity on planet Earth. With a depth of order one kilometer, the physics governing profiles of wind, temperature, and gases can be represented in terms of a small number of key turbulent processes framed by Monin–Obukhov similarity (MOS) theory. This article summarizes the assumptions and applications of MOS theory to the surface layer, and key scientific challenges are summarized where MOS theory is exposed to conditions that violate basic assumptions.

Introduction

The lowest layer of the atmosphere, the surface layer, directly influences the daily activities of nearly all life on planet Earth. Extending up to an altitude of order 50–100 m, the surface layer possesses dynamical, physical, and chemical characteristics long recognized as having a controlling influence over a wide range of human and societal interests. For example, even as early as 600 BC, the force of the wind acting against the flow of the Nile was already being used as a secondary process included in flood forecasts in ancient Egypt. About 2000 years ago, simple climatologies of near-surface wind directions were the basis of weather forecasts in the Mediterranean, for use in both military and commercial activities. By the late Middle Ages in both Europe and China, sailing ships were being designed to exploit the greater wind speeds, which regularly were observed at increasing heights above the surface. In fact, the Chinese used kites to study surface layer wind profiles as early as 1400 years ago. More recently, i.e., in the early twentieth century, pollutant dispersion models were developed, based on anthropogenic emissions from point sources (such as smokestacks) and compiled wind statistics, in order to estimate pollutant concentrations at different distances downwind. Some of the greatest challenges we face today in areas such as remote sensing involve understanding the relationship between the surface layer and the underlying terrestrial biosphere and oceans.

The role of the atmospheric surface layer in surface energy exchanges is an essential ingredient in understanding both local and global climatology. The dominant local process governing the surface layer energy balance is a large downward flux of solar radiation, absorbed at the earth's surface during the day that in turn is converted rapidly to heat. While some of the surface heat energy is transferred down into the surface canopy and soil system, a significant fraction of the heat is transferred vertically upward into the surface layer. If the surface layer is highly turbulent (as it is during most afternoons), the upward flux of heat is highly efficient, thus leading to significant vertical mixing. In stark contrast, e.g., during calm clear nights, turbulence is often suppressed, thus leading to minimal vertical transfer of heat and the more extreme cold nights often observed, e.g., in midwinter. Note that if the nocturnal surface layer is otherwise windy, the associated higher turbulence levels can provide an efficient mechanism for transferring heat rapidly down to the surface, thus reducing the rate of nighttime cooling. From both

a scientific and a societal perspective, it is the presence or absence of turbulence in the surface layer which acts as a control over the degree to which humans and surface-based ecosystems are exposed to diurnal and climatic extremes.

Surface Layer: Turbulence, Eddies, and Logarithmic Profiles

In the atmospheric sciences, the depth of the surface layer is, by convention, defined as 10% of the depth of the full planetary boundary layer (PBL). This implies that the surface layer can range from 10 m height up to 150 m height, depending in most part on the mixing rates and degree of large-scale convection or subsidence. Within the surface layer, quantities such as wind speed, temperature, and humidity vary significantly with height; above the surface layer, these quantities tend to approach more constant values with height until one reaches the inversion that overlies the PBL.

The surface layer is also defined as the lowest layer of the atmosphere where the vertical scales of all of the turbulent eddies are limited by proximity to the surface, thus all surface layer turbulent eddies will have length scales that on average are proportional to height above the surface. It is this basic assumption when combined with information on turbulence spectra that allows one to derive the characteristic logarithmic wind, temperature, and humidity profiles, as well as the various sampling methodologies to obtain turbulent fluxes within the surface layer.

The derivation of the wind, temperature, and humidity profiles start with the assumption that the wind vector can be represented with a mean downstream velocity, $\langle U \rangle$, and its fluctuating component, u' , i.e.,

$$U = \langle U \rangle + u' \quad [1]$$

In analogy, one can also write the vertical velocity as,

$$W = \langle W \rangle + w' \quad [2]$$

Since the downstream component of the vertical momentum flux, τ , normalized by density, ρ , may be expressed as $(\tau/\rho) = -UW$, one may combine with eqns [1] and [2] to easily arrive at $(\tau/\rho) = \langle -u'w' \rangle$. For this expression, the averaging time be long enough so that $\langle W \rangle = 0$. Furthermore, in this expression, it is a common practice in the atmospheric sciences to assume that momentum flux is positive downwards. With

this practice, the vertical momentum flux may also be assigned a characteristic friction velocity, u^* , such that:

$$u^{*2} = \langle -u'w' \rangle \quad [3]$$

While field observations have generally shown that the value of u^* is nearly constant with height within the atmospheric surface layer, the reality is that u^* must be allowed to vary by up to 10% of its surface value. In addition, while the mean cross-stream velocity is defined to be 0, there is sometimes a small $\langle -u'v' \rangle$ contribution to u^{*2} , such that the momentum flux vector and wind vector are no longer aligned.

The next step in the derivation of wind, temperature, and humidity profile relations is based on similarity laws applied to engineering studies of flow over plates. Here we invoke the assumption that an eddy viscosity coefficient K_m developed from flows over flat plates may be applied to the atmospheric surface layer, such that

$$K_m \partial U / \partial z = u^{*2} \quad [4]$$

Letting K_m be defined by the Prandtl mixing length hypothesis, i.e., $K_m = \langle h'^2 \rangle |\partial U / \partial z|$, where h' is the turbulent mixing length, and letting h' be proportional to height above the surface, z , eqn [4] may now be rewritten as:

$$\partial U / \partial z = u^* / kz \quad [5]$$

where k is the von Karman constant. Integration of eqn [5] over z leads to the classical logarithmic wind speed profile:

$$U = (u^* / k) \ln [z / z_0] \quad [6]$$

where z_0 is the roughness length. In analogy to eqn [6], the vertical profile of temperature and humidity may also be derived and will exhibit a logarithmic behavior.

The logarithmic nature of profiles has over the years become a defining feature of the atmospheric surface layer, and measurements have corroborated eqn [6] and similar equations for heat and moisture for near neutral stratifications. A major limitation of the early profile relations was a theoretical deficiency for treating nonneutral stratifications, and more recent limitations are associated with the roles that non-stationarity, spatial heterogeneity, discontinuities, internal boundary layers, and local flux divergence.

Surface Layer Profiles, Fluxes, and Stratification

During the 1950s, the Monin–Obukhov similarity (MOS) theory emerged as a major theoretical development able to address the influence of atmospheric stratification on the logarithmic profiles and fluxes (Monin and Obukhov, 1954). These investigators began their analysis by determining which terms of the turbulent kinetic energy (TKE) equation were the most important controls over atmospheric mixing rates, and they used the results of their analyses to construct an appropriate stratification parameter.

Most commonly written in the following form, the TKE budget is:

$$\begin{aligned} \partial e / \partial t = & -U \partial e / \partial x - \langle u'w' \rangle \partial U / \partial z - \partial \langle w'e' \rangle / \partial z \\ & - \rho^{-1} \partial \langle w'p' \rangle / \partial z - (g/T_v) \langle w'T_v' \rangle - \nu \langle (\partial u_i' / \partial x_i) \\ & \times (\partial u_i' / \partial x_i) \rangle \end{aligned} \quad [7]$$

In eqn [7], the quantities u' , v' , and w' represent the fluctuating downwind (x -direction), crosswind (y -direction), and vertical (z -direction) wind velocity components. The parameter e is TKE per unit volume (E), normalized by density; the instantaneous contribution to the TKE may be denoted as $e' = 1/2 u_i' u_i'$. The virtual temperature, T_v , is defined as $T(1 + 0.61q)$, where T is temperature and q is humidity. The first term on the right hand side (r.h.s.) of eqn [7] represents the rate of change of TKE due to advection. The second term represents shear production. The third term is the flux divergence of TKE, while the following term is the divergence of pressure flux. The fifth term on the r.h.s. is TKE production or loss due to buoyancy, and the last term is the loss of TKE due to viscosity, i.e., the dissipation rate. If conditions are steady state and horizontally homogeneous, and letting the dissipation rate be represented by ε , eqn [7] is simplified to:

$$0 = -\langle u'w' \rangle \partial U / \partial z - (g/T_v) \langle w'T_v' \rangle - \varepsilon - R \quad [8]$$

where the imbalance terms are combined as $R = \rho^{-1} \partial / \partial z (\langle w'p' \rangle + \rho \langle w'e' \rangle)$; most investigators assume that the combination of imbalance terms is small enough to be ignored. Substituting eqn [5] into eqn [8], a dimensionless stability parameter was introduced, based on the ratio of the shear-induced TKE to the buoyancy-induced TKE, i.e.,

$$z/L = gkz \langle w'T_v' \rangle / T_v u^{*3} \quad [9]$$

The quantity L is hereinafter referred to as the Monin–Obukhov length.

For wind speed and temperature profiles, estimates of profile gradients could account for variations in atmospheric stratification, i.e.,

$$\partial U / \partial z = (u^* / kz) \phi_U \quad [10a]$$

$$\partial T / \partial z = (T^* / kz) \phi_T \quad [10b]$$

where the functions ϕ_U and ϕ_T are formulated in terms of z/L .

Integration of eqn [10a] and [10b] over height yields logarithmic profiles of wind speed and temperature, i.e.,

$$U - U_0 = (u^* / k) \{k \ln (z/z_0) - \Psi_U\}^{-1} \quad [11a]$$

$$T - T_0 = (T^* / k) \{k \ln (z/z_{0T}) - \Psi_T\}^{-1} \quad [11b]$$

where Ψ_U and Ψ_T are stability functions that are related to ϕ_U and ϕ_T , z_0 and z_{0T} represent roughness lengths for momentum and temperature, and $T^* = \langle w'T' \rangle / u^*$. For neutral stratifications, i.e., where $\partial T_v / \partial z = 0$, the quantities Ψ_U and Ψ_T equal 0; positive/negative values of Ψ_U and Ψ_T correspond to unstable/stable stratifications. The functional relationships between ϕ_U and Ψ_U as well as between ϕ_T and Ψ_T may be found in most references following this article.

The Bulk Aerodynamic Relationships

For many of the more important applications of surface layer theory to, e.g., pollution dispersion, atmospheric and oceanic modeling, loads on structures, and remote sensing inversion algorithms, estimates of the surface fluxes based on easily obtained observations of mean surface layer quantities (such as

wind speed, temperature, etc.) are highly desirable. It was partly to satisfy these needs that similarity theory was developed.

Rearrangement of eqn [11a] and [11b] yields the bulk aerodynamic relations for momentum and temperature fluxes, e.g.,

$$u^{*2} = C_D(U - U_0)^2 \quad [12a]$$

$$u^*T^* = C_H(U - U_0)(T - T_0) \quad [12b]$$

where the quantities C_D and C_H are respectively the drag coefficient and the Stanton number, i.e.,

$$C_D = [k/\ln(z/z_0) - \Psi_U]^2 \quad [13a]$$

$$C_H = [k/\ln(z/z_0) - \Psi_U][k/\ln(z/z_T) - \Psi_T] \quad [13b]$$

A similar relation can be derived for the humidity profile and its coefficient, the Dalton number.

The beauty of the derivation of the drag and other flux coefficients is that they, at least in theory, do not depend on wind speed and are weakly dependent on height, roughness, and typical ranges of atmospheric stratification. We note herein that strongly stable stratifications do, in fact, lead to much smaller flux coefficients, i.e., when compared with neutral or unstable conditions. In the experimental literature, the coefficients are often normalized to values representative of neutral stratifications (e.g., C_{DN} and C_{DH}) and for a standard height of 10 m above the surface so that they may be easily compared to other data sets and/or integrated into models as general parameterizations. Details of the relationships between the flux coefficients and their neutral stratification counterparts are summarized in Geernaert (1999).

Sampling of Fluxes in the Surface Layer

Most modern research into the characteristics of the surface layer has relied on very complicated measurements collected over a wide variety of wind, stratification, and roughness conditions. Flow distortion, platform motions, and the simplifying assumptions associated with specific methods have made both the measurements and subsequent interpretations of data difficult. Until the 1970s, the most common method of gathering surface layer flux data was based on vertical profiles of the average wind speed, temperature, and humidity. This method relied on the rearrangement of eqn [11] into a form where plots of wind speed vs the natural logarithm of height yielded information on the friction velocity and surface roughness simultaneously. As an example, for wind speed, the slope is (u^*/k) and the bias is $[(u^*/k)(\ln\{z/z_0\} + \Psi_U)]$ when one plots data in a form where $(x, y) = (U - U_0, \ln z)$.

During the 1970s and 1980s, the newly developed sonic anemometer and other fast-response instruments for measuring temperature and humidity rapidly replaced the profile technique, thus making possible directly measured turbulent fluxes using eddy correlation. The turbulent fluxes, i.e., $\langle u'x' \rangle$, where x' is either the fluctuating component of wind speed, temperature, or gas, could now be easily computed with field observations, as long as fluctuations at altitudes of order 10 m could be sampled at 5 Hz or more and the

averaging time was long enough that $\langle W \rangle$ is negligible. To guarantee that $\langle W \rangle$ is sufficiently small, it is a routine practice to sample the domain for at least 30 min and much longer during stably stratified conditions.

Much of the recent scientific progress in understanding the dynamics governing turbulence spectra, asymmetric turbulence, coherent structures, intermittency, and internal boundary layers was made possible with rapid sampling techniques that were led by the sonic anemometer and other fast-response instruments. The inertial subrange of surface layer turbulence was also discovered with these methodologies to have uniquely identifiable surface layer properties and scaling laws, and this discovery helped drive a major body of surface layer research starting during the 1970s and 1980s. Relevant for eddy length scales of order 1 cm up to order 10 m, the TKE density, $S(k_\lambda)$, within the inertial subrange was discovered to follow a $-5/3$ wavenumber (k_λ) power law:

$$S(k_\lambda) = \alpha \varepsilon^{2/3} u^{*2} k_\lambda^{-5/3} \quad [14]$$

where the quantity ε is the TKE dissipation rate and α is an accepted value of 0.52.

During the 1980s and 1990s, the application of eqn [14] to the dissipation method became a popular sampling technique especially for overocean research, owing to the relative insensitivity of this method to the platform motions. The dissipation method also requires shorter averaging time than for the eddy correlation technique, thus giving it an added advantage. For the case of momentum fluxes, the dissipation method is easily derived from the combination of eqns [14] and [10a]; by ignoring R and assuming near neutral stratifications, one obtains:

$$S(k_\lambda) = \alpha(kz)^{-2/3} u^{*2} k_\lambda^{-5/3} \quad [15]$$

A simplified form of the TKE budget may now be expressed as $u^{*3} = kz/\Phi_e$. Using empirical functions that describe Φ_e (referring to references at the end of this article), one-dimensional spectra of horizontal wind speeds easily produces estimates of u^* with this technique.

In addition to momentum, the dissipation method has been applied to infer temperature, water vapor, and carbon dioxide fluxes. As techniques begin to emerge for other compounds that have had difficulty sampling with very high frequency, the dissipation method will no doubt gain popularity across a broad range of species and applications. The challenges, however, remains how to deal with imbalance terms in both the TKE budget and the variance budgets for temperature and gaseous compounds, particularly if the domain of interest exhibits substantial spatial variability (e.g., in coastal zones).

Trace Gas Exchange

Simple models for the surface exchange of trace gases exhibit more complexity than the bulk aerodynamic relations described in the previous sections. Not only does turbulent transfer in the surface layer play a key role, but one must consider the reactions of the compound with both other atmospheric species and with the surface. For chemical compounds that have reaction time scales, which are long

compared with surface layer turbulence time scales, the constant flux layer assumption may be invoked. This applies to gases such as CO_2 , O_2 , and SO_2 . However, if the reactions are relatively fast, in particular with respect to the time scales of surface layer turbulence, a flux divergence of the particular compound will occur. Species such as HNO_3 and NH_3 are examples, and the following equation must be solved in this case:

$$U \partial c / \partial x + \partial \langle w'c' \rangle / \partial z = S \quad [16]$$

In eqn [16], S represents a production or loss of chemical concentration, c , based on chemical reactions. Because of the risk of other processes, which are more important than turbulent transport, this balance tests the limits of similarity theory applicable to the surface layer. In spite of this shortcoming, the scientific community has proceeded to produce a body of literature in which many of the limiting assumptions can be relaxed if one can use reference heights which are closer to the surface, i.e., where characteristic turbulence time scales are much smaller.

An alternative approach to measuring gas fluxes is based on the concept of the deposition velocity, v_d . Here one uses various additive resistances associated with the flow of compound, c :

$$v_d = \langle w'c' \rangle / (c - c_s) = (r_a + r_b)^{-1} \quad [17]$$

where r_a is the aerodynamic resistance governing turbulent transport of species c ; and r_b is the surface resistance, governing the diffusion transport over the laminar sublayer. While the surface concentration, c_s , is set to 0 for many gases, there are others such as the biogenic reactive gases (e.g., NH_3) that can exhibit high surface concentrations; in these cases, the surface concentrations need to be estimated based in part on models of surface biological activity. In essence, eqn [17] implies that the turbulent transport associated with r_a represents the maximum possible deposition velocity for any species undergoing air-surface exchange ($=1/C_D U$), and r_b is a correction factor that depends on the properties of the particular compound undergoing air-surface exchange. The surface resistance, r_b , is more difficult to describe. The quantity r_b is based on the two key assumptions: that there exists a relatively homogeneous laminar sublayer at the surface; and that the physical characteristics of the surface and the biological characteristics govern the rate of diffusion.

Flux Profile Relations for Quasi-Inhomogeneous Conditions

Applications of MOS theory generally require that the surface layer be characterized by spatially homogeneous and steady state conditions, and that the vertical fluxes within the surface layer are nearly constant with height. In recent years, however, a new class of scientific and engineering problems has emerged, where some of the requirements, most notably spatial homogeneity, need to be relaxed. Examples of such new problems include understanding the role of internal boundary layers on turbulence profiles associated with offshore wind farms, and evaluating subgrid surface layer variabilities within the much finer resolution atmospheric and oceanic models. Several

modified theories have been introduced to examine MOS theory under spatially heterogeneous or nonstationary conditions, some of which employ results of large eddy simulations while others explore the use of 'flux footprints' and local internal boundary layers.

In a recent study, Geernaert (2010) produced a modified form of MOS theory, applicable to quasi-homogeneous and nonstationary conditions. Assuming that advection and nonstationarity can act as proxies of external forcing that lead to local deviations of similarity theory, eqn [8a] may be rewritten into a more general form:

$$\partial U / \partial z = u^* / kz (\phi_u + H^* + J^*) \quad [18]$$

where H^* and J^* are functions that describes respectively the spatial and temporal variabilities of wind speed. Integration of eqn [18] over z will yield a drag coefficient expression that is much more complicated than eqn [13a]. In this case, the drag coefficient that is normalized for neutral stratification, horizontal homogeneity, and stationarity, i.e., C_{DR} , will be significantly different from the drag coefficient that is normalized only for neutral stratifications, C_{DN} :

$$C_{DR}^{-1/2} = C_{DN}^{-1/2} - \left\{ (z/2U) C_D^{-3/2} \right\} \left\{ \left(1 - \left[\xi C_D^{1/2} / k \right] \right) \partial U / \partial x + U^{-1} \partial U / \partial t \right\} \quad [19]$$

Analogous to eqns [18] and [19], spatial inhomogeneity and nonstationarity introduces more complicated flux profile expressions and flux coefficients for temperature, humidity, and reactive gases. See Geernaert (2010) for a review of the derivations.

Challenges and New Directions

The state of our present knowledge of the surface layer has been built from the similarity paradigm introduced in 1954 by Monin and Obukhov. This theory proved quite successful, particularly for inferring fluxes or profiles averaged over spatial scales which are greater than 25 km and temporal scales of order 1 h or more. During recent years, however, the scientific challenges given by mesoscale and boundary modelers and other applied customers involve scales up to three orders of magnitude smaller than those that the research community explored even two or three decades ago. Obviously, the problems of determining the momentum flux to swell and wind waves, and the problem of estimating fluxes for reactive gases (e.g., ammonia, nitric oxide, ozone, etc.) deposition patterns near, e.g., the edge of sensitive forested ecosystems, are good examples where the basic assumptions of similarity theory have become routinely violated. For this reason, one may expect that studies of surface layer theory will soon enter a new era, where advanced modeling and *in situ* measurement techniques will need to be combined with multiscale *in situ* and remote sensing systems.

Synopsis

It is estimated that by the year 2025, 80% of the world's population will live in cities. This conversion of the natural landscape vegetation into man-made urban structures such as roads and buildings drastically alter the regional surface energy budgets, hydrology, precipitation patterns, and meteorology. Research studies from many cities have documented that these effects range from decreases in air quality, increased energy consumption, and alteration of regional climate to direct effects on human health.

Introduction

It is estimated that by the year 2025, 80% of the world's population will live in cities. The extent of these urban areas across the world can be seen in an image of city lights from the Defense Meteorological Satellite Program (Figure 1). In many areas of North America and Europe, it is difficult to separate individual cities because of the dramatic growth and sprawl of urbanized areas. This conversion of the natural landscape vegetation into man-made urban structures such as roads and buildings drastically alter the regional surface energy budgets, hydrology, precipitation patterns, and meteorology.

One of the earliest recognized and measured phenomena of urbanization is the urban heat island (UHI) which was reported as early as 1833 for London (Howard, 1833) and 1862 for Paris. The UHI results from the energy that is absorbed by man-made

materials during the day and is released at night resulting in the heating of the air within the urban area. The magnitude of the air temperature difference between the urban and surrounding countryside is highly dependent on the structure of the urban area, amount of solar insolation received during the day, and atmospheric conditions during the night. These nighttime air temperature differences can be in the range of 2–5 °C (Figure 2). Daytime air temperature differences between urban areas and the countryside may exist during the day; however, atmospheric mixing and instability reduce the magnitude. This phenomena is not limited to large urban areas, but also occurs in smaller metropolitan areas. The UHI has significant impacts on the urban air quality, meteorology, energy use, and human health. The UHI can be mitigated through increasing the amount of vegetation and modification of urban surfaces using high albedo materials for roofs and paved surfaces.

Figure 1 This image of Earth's city lights was created with data from the Defense Meteorological Satellite Program (DMSP) Operational Linescan System (OLS). Originally designed to view clouds by moonlight, the OLS is also used to map the locations of permanent lights on the Earth's surface. Urban Surface Energy and Radiation Budget

To understand why the UHI phenomena exists, it is useful to define the surface in terms of the surface energy budget. Surface temperature and albedo are major components of the surface energy budget. Knowledge of it is important in any attempt to describe the radiative and mass fluxes that occur at the surface. Use of energy terms in modeling surface energy budgets allows the direct comparison of various land surfaces encountered in an urban landscape, from vegetated (forest and herbaceous) to nonvegetated (bare soil, roads, and buildings). These terms are also easily measured using remote sensing from aircraft or satellite platforms allowing one to examine the spatial variability of the urban surface. The partitioning of energy budget terms depends on the surface type. In natural landscapes, the partitioning is dependent on canopy biomass, leaf area index, aerodynamic roughness, and soil moisture status, all of which are influenced by the regional climate. In urban landscapes, coverage by man-made materials substantially alters the surface energy budget.

The net all-wave radiation balance (W m^{-2}) of landscape canopies can be determined following:

Net solar radiation, K^* , is given by

$$K^* = (1 - \alpha)(K\downarrow) \quad [1]$$

where α = site albedo and $K\downarrow$ = incoming solar radiation.

Albedo is defined as

$$\alpha = \frac{K\uparrow}{K\downarrow} \quad [2]$$

where $K\uparrow$ = reflected solar radiation.

The long wave energy ($L\uparrow$) emitted from a surface is dependent on surface temperature:

$$L\uparrow = \epsilon[\rho T^4] \quad [3]$$

where ϵ = emissivity, ρ = Stefan-Boltzman constant ($5.7 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$), and T = land surface temperature (K).

The net long wave radiation at the surface is given by

$$L^* = L\downarrow - L\uparrow \quad [4]$$

where $L\downarrow$ = long wave radiation from the atmosphere (mostly due to water vapor).

Therefore, the net all-wave radiation, Q^* , can be given as

$$Q^* = K^* + L^* \quad [5]$$

Net radiation is a particularly useful term because, under most conditions, it represents the total amount of energy available to the land surface for partitioning into nonradiative processes (mass heating, evapotranspiration, biological synthesis, etc.) at the surface. In vegetated areas the amount of net radiation is dependent upon vegetation type and varies with canopy leaf area and structure.

Net radiation may be expressed as the sum of these non-radiative fluxes:

$$Q^* = LE + H \pm G \quad [6]$$

where LE = latent heat flux (both transpiration by plants and evaporation), H = sensible heat flux, and G = energy flux into or out of storage (both vegetation, urban materials, and soil).

The partitioning of LE , H , and G are dependent on the surface composition. Vegetation canopies (leaf stomata) can control transpiration rates over a wide range of soil moisture conditions and atmospheric vapor deficits. Both the physiological control of moisture loss (stomatal resistance) and leaf/canopy morphology for vegetation determines how Q^* is partitioned among LE , H , and G . In urban areas, the combination of both man-made materials and vegetation results in a spatially variable, heterogeneous mixture of surfaces that produce a complex, range of surface albedo values and significant differences in the partitioning of the surface energy budget.

The change in surface temperature as a function of time is an additional property that can be measured using remotely sensed data. Usually a separation of about 30 min results in a measurable change in surface temperature caused by the change in incoming solar radiation. Their ratio can be used to define a surface property called the thermal response number (TRN) (Luvall and Holbo, 1989):

$$\text{TRN} = \frac{\sum_{t_1}^{t_2} (Q^*)(\Delta t)}{\Delta T} \quad [7]$$

where $\sum_{t_1}^{t_2} (Q^*)(\Delta t)$ is total net radiation and ΔT change in surface temperature for time period t_1 – t_2 .

The TRN provides an analytical framework for studying the effects of surface thermal response for large spatial resolution map scales that can be aggregated for input to smaller scales, as

needed by climate models (Comarazamy et al., 2013b). The importance of TRN is that (1) it is a functional classifier of land cover types; (2) it provides an initial surface characterization for input to various climate models; (3) it is a physically based measurement; (4) it can be determined completely from remotely sensed data; and (5) it is a scale-independent measurement that can be examined from a pixel-by-pixel measurement or by extracting a polygon from the landscape feature containing multiples of pixels representing the required element. The TRN can be used as an aggregate expression of both surface properties (vegetation canopy structure and physiological condition; urban structures and material types) and environmental energy fluxes.

The remotely sensed data obtained from the aircraft and satellite, when properly calibrated allows the measurement of important terms in the radiative surface energy budget: $K\uparrow$ and $L\uparrow$ on an urban landscape scale. Additional radiative balance terms $K\downarrow$, $L\downarrow$, and Q^* can be determined by modeling atmospheric radiance properties using radiosonde data and shadow band radiometers with atmospheric models such as MOD-TRAN4 (Berk et al., 1999).

Although satellite data are very useful for analysis of the UHI effect at a coarse scale, they do not lend themselves to developing a better understanding of which surfaces across the city contribute or drive the development of the UHI effect. Analysis of thermal energy responses and energy budgets for specific or discrete surfaces typical of the urban landscape (e.g., asphalt, building rooftops, vegetation) requires measurements at a very fine spatial scale (i.e., <15 m) to adequately resolve these surfaces and their attendant thermal energy regimes. Additionally, very fine scale spatial resolution thermal infrared data, such as that obtained from aircraft, are very useful for demonstrating to planning officials, policy makers, and the general populace the benefits of planning cool communities. These benefits include mitigating the UHI effect, making cities more aesthetically pleasing and more habitable environments, and sustainable communities (Quattrochi et al., 2000).

It is important to understand the partitioning of surface energy budget given in eqns [1] and [6] and its role in determining actual surface temperatures. A significant UHI mitigation strategy is to increase the city's albedo to reduce roof and pavement warming. Equation [6] shows that there are only three pathways, which the energy from net radiation can take: (1) evaporate water (latent heat); (2) warm the air (sensible heat); and (3) reach the ground (storage). Forest vegetation has a low albedo value, similar to many rooftops. Its surface temperature may be much cooler than a roof because the energy absorbed by the surface is partitioned into latent heat (cooling the surface) rather than sensible heat (surface heating). An asphalt surface may not get as hot as a rooftop, but the energy is going into storage and released overnight. These basic principles must be understood in order to make intelligent decisions when incorporating the UHI mitigation strategies to both urban heating and air quality issues.

High spatial resolution visible and thermal data are required to quantify how artificial surfaces within the city contribute to an increase in urban heating and the benefit of cool surfaces. One good example is Atlanta, a large southeastern US city, which illustrates the complexity of surfaces found in a city. A NASA project using an airborne multispectral visible and thermal scanner (ATLAS, airborne thermal and land applications sensor) collected 10 m resolution data over Atlanta, Georgia, on 11 and

12 May 1997. These data were collected around solar noon (maximum surface heating) and about 5 h after sunset. The day was clear and cloud free. The maximum daytime air temperature was 25.5 °C and the nighttime minimum was 14.4 °C. Atlanta central business district albedo (Figure 3) averaged a low value of 0.18. The lower albedo values (0.10–0.13) consisted of vegetation and asphalt roads. A few high albedo areas were white membrane rooftops. Daytime surface temperatures (Figure 4) indicated that the greatest temperatures were the roofs (45 °C), followed by asphalt parking lots and roads. Areas of vegetation and water were the coolest, at around 22 °C. The overall average for the area is 31.7 °C. After sundown (Figure 5) it becomes evident what areas of the city store the sun's energy and slowly release it at night. The roofs are the hottest surfaces during the day, but have little thermal mass and cool off quickly. Asphalt roads and parking lots, and concrete buildings have large thermal mass and cool off much more slowly. The overall average surface temperature about 5 h after sunset was 14.7 °C. We see that the core central business district is much warmer, about at 16.6 °C and a nearby residential area was 15.0 °C. One can understand the importance of how the city is designed will influence greatly the magnitude of the UHI effect, along with the prevailing meteorological conditions.

Table 1 allows the comparison among other US cities for albedo, net radiation, surface temperature, change in surface temperature over time and the TRN for four different land use types. Generally, the industrial areas had the highest albedo and the hottest temperatures, indicating little or no vegetation. In contrast, the albedo of urban parks was low and the surface temperatures were the coolest, indicating a well-watered vegetated surface. The partitioning of Q^* can be evaluated

Park	0.260	316	30.8	4.1	299

EPA Urban Heat Island Project.

using the TRN. The greater the TRN the more energy is being used to evaporate water rather than to heat the air. For example, the Park in Baton Rouge has a TRN of $5903 \text{ kJ m}^{-2} ^{\circ}\text{C}^{-1}$ and a small ΔT over the measurement period. In other areas the ΔT is much greater and the TRN is

smaller. In Salt Lake City the park TRN is only $299 \text{ kJ m}^{-2} ^{\circ}\text{C}^{-1}$ compared to $701 \text{ kJ m}^{-2} ^{\circ}\text{C}^{-1}$ for the park in Sacramento and ΔT of $4.1 ^{\circ}\text{C}$ and $2.2 ^{\circ}\text{C}$, indicating that less of the surface energy is being partitioned into latent heat flux and more into heating the air. It appears that the vegetation cover in the Salt

Figure 6 A scattergram of surface temperatures and albedo produced from NASA's airborne ATLAS scanner 10 m resolution data of Salt Lake City, UT.

Lake City park was not transpiring (latent heat flux) as much as the vegetation in Baton Rouge or Sacramento.

Since albedo alone does not truly reflect how the urban surface partitions energy, one needs additional information to access the 'urban fabric' of the city. Including surface temperature provides the needed additional information. Aircraft- or satellite-based remotely sensed data sets provide the needed calibrated and quantifiable data sets in physical units. Since we are working in physical units, the TRN, surface temperature and albedo classifications represents a functional classification of that surface, that can readily be incorporated into the surface parameterization of meteorological and air quality models.

A city has a distinctive 'energy print' that is a characteristic of its surface composition and processing energy (Figure 6). For example a park, i.e., dark and cool, shows up quite nicely in Salt Lake in the lower left corner of the scattergram. These scattergrams become a very powerful classification tool representing the functional classification of urban land surfaces. Within each city, each land use has a unique 'energy print' that is directly physically related to how that surface is processing energy. These 'energy prints' of the land use are unique for each city; i.e., the Sacramento central business district (CBD) scattergram is significantly different than Baton Rouge or Salt Lake City's CBD scattergram. These results again emphasize that classifications based on cover type/land use cannot be applied across a variety of cities, since they cannot represent the true energy partitioning of that surface.

Urban Growth Modeling

Urban growth models provide a tool for cities to project future conditions based on existing trends or policy modifications such as implementation of higher density development policies and preservation of environmentally sensitive areas. These future scenarios are also useful as input to physical models designed to evaluate the effect of urbanization changes to air quality and other environmental conditions.

Growth models may be applied at a variety of scales and are broadly grouped into either empirical or dynamic process simulation models. Empirical models strive to statistically match temporal trends and/or spatial variables with a set of predictor variables, whereas dynamic process models seek to represent the most important interactions among people and the environment. Cellular automata models are examples of process models (Brown et al., 2004). The Prescott Spatial Growth Model (PSGM) is an emerging dynamic process growth model that operates on a geographic information systems platform. The PSGM allows users to design future conditions by developing rules and priorities for the model to determine the future allocation of vacant land for development. The primary drivers of the quantity of future developed land are population and employment projections (Estes et al., 2010).

The PSGM was used to develop future urban scenarios in the Atlanta Metropolitan area and coupled with air quality models to determine the future impact on ozone levels and the potential benefit of proposed mitigation strategies. Results enable policy makers to determine both magnitude and spatial changes in the projected UHI and the environmental benefits of mitigation strategies. Also, future projections will benefit planners in the development of State Implementation Plans required for areas in air quality nonattainment (Quattrochi et al., 2006).

Impacts of the Urban Heat Island

The UHI has significant impacts on our urban environment. Research studies from many cities have documented that these effects range from decreases in air quality, increased energy consumption, and alteration of regional climate to direct effects on human health (Jacob and Winner, 2006; Stone, 2008).

One of the major air quality concerns is summertime ozone levels. Ozone is produced from a photochemical reaction requiring sunlight (UV component), various nitrogen oxide compounds (NO_x , derived from combustion processes), and complexes of volatile organic compounds (derived from vegetation and petrochemical products). The rate of ozone production is sensitive to the increase in air temperature and higher surface temperatures increase the amount of precursors evolved from the surface (Vukovich et al., 1979). Wintertime effects from the UHI on air quality have also been documented in Tokyo, Japan (Yoshikado and Tsuchida, 1996). The winter heat island disrupt the land-sea breeze and results in higher concentrations of air pollutants remaining over the city for longer periods of time by blocking the sea-land breeze. The UHI maintains a temperature gradient down to the inland area, thus tending to reinforce the sea breeze in the shore area and prevent it from penetrating through the urban area. This convergence zone tends to remain over urban areas for several hours.

The UHI results in overall increased energy usage by cities, particularly a large increase in the peak power demands. Calculations done by Lawrence Berkeley Laboratory found that for Los Angeles for every 1 °C increase in air temperature there was a 2.9% increase in power requirements. Since most electrical energy is produced by the combustion of fossil fuels, there is an increase in NO_x released into the urban environment thus adding to the production of ozone (Akbari et al., 1999, 2001; Akbari and Konopacki, 2005; Ashley et al., 2012; Taha, 2007).

Alterations of regional weather patterns caused by the UHI have been well documented. One of the major alterations linked to the UHI is the change in the quantity, location, and timing of precipitation in the region surrounding the urban areas caused by UHI-induced convergence processes (Shepherd et al., 2010). Generally, precipitation is increased downwind from urban areas. Studies from New York City, New York, showed lines of local convective thunderstorms originating in New Jersey during summer afternoons split into two halves that pass north and south of New York City (Loose and Bornstein, 1977). A time series of visible data (1 km resolution) collected from GOES8 for Atlanta during 3 August 1996 show the development of thunderstorms caused by the convergence initiated by the city (Figure 7) (Bornstein and Lin, 2000).

The impact of 'mega cities' in exacerbating regional heat effects can be important. Zhang et al. (2009) using a combination of ultrahigh resolution numerical simulations as fine as 500 m using a multinested (0.5, 1.5, 4.5, and 13.5 km) version of the Weather Research and Forecasting (WRF) model, a single-layer urban canopy model, and the National Land Cover Data found a significant increased UHI contribution resulting from adjacent urbanization 'upstream.' They found (modeled) that when upstream urbanization was replaced by natural vegetation UHI effects could be reduced by more than 25%.

Urbanization in island tropical cities have significant climate impacts in tropical coastal regions with the added complexity of occurring within the context of a warming climate. Comarazamy et al. (2013a) investigated the individual and combined effects of these two factors in tropical islands by use of an integrated mesoscale atmospheric modeling approach (Regional Atmospheric Modeling System) and high resolution ATLAS (10 m) data, using the northeastern region of

Puerto Rico as the test case. An ensemble of climate simulations was performed, combining two land cover land use (LCLU) and global warming scenarios. The authors show that LCLU changes produced the largest near-surface (2-m above ground level.) air temperature differences over heavily urbanized regions and that these changes do not extend into the boundary layer. The simulated influence of the global warming signal induced a positive inland gradient of maximum temperature and increased trade winds that impacted convergence zones and the resulting convection that transport heat and moisture into the boundary layer. Minimum temperatures were also increased along the coastal plains and inland lowlands.

Other meteorological impacts caused by the UHI include suppression of weak tornadoes and an increase in lightning. Studies starting in 1957 from England and Wales found that within 10 km of London there is a suppression of weak tornadoes (Olfe and Lee, 1971; Elsom and Terence Meaden, 1982). Research examining lightning for a 12-year period around Houston, Texas, reported a significant enhancement in lightning for both summer and winter centered over and downwind of the urban area (Orville et al., 2001; Ashley et al., 2012). The result of the UHI encouraging convection and the mechanical effect of the urban heat fabric causing frictional convergence are generally believed to be the most important factors responsible.

Although urbanization of natural vegetated areas is the most significant factor in creating the UHI, local and regional weather patterns determine the intensity of the UHI effect. Hu et al. (in review) using surface meteorological observations coupled with WRF simulations of Oklahoma City determined that low-level jets (LLJs) were critical in moderating the nocturnal UHI intensity and extent. Presence of a strong LLJ increased vertical mixing and instability reducing the UHI

Figure 7 Thunderstorm development caused by Atlanta, Georgia's urban heat island induced convergence. GOES8 images are from 3 August 1996 starting at 1615UT. Images courtesy of Stan Kidder, Cooperative Institute for Research in the Atmosphere, Colorado State University.

intensity. Weak LLJ produced less vertical mixing and a shallow, stable boundary layer which increased the UHI.

Heat stress kills more people worldwide than any other weather phenomenon, including cyclones and floods, according to the World Meteorological Organization (WMO). Deaths rise by over 50% on average during heat waves. The UHI is a significant factor of heat stress experienced by the urban population (Gaffen and Ross, 1998). Every summer in the United States, heat stress directly causes about 2000 deaths. WMO statistics reveal the heat also is indirectly blamed for many other deaths, most from heart attacks, strokes, and other heat-related problems. The death rate during heat waves can triple in cities like New York, where the number of heat-related deaths jumped from an average of 490 to 1260 during a single 24-h period in 1966. In Chicago, the heat wave in the summer of 1995 caused at least 700 deaths (Karl and Knight, 1997). It is readily apparent from Figure 5 how the partitioning of the sun's energy into storage within the urban areas impact nighttime temperatures and increase the heat stress in the urban population.

Mitigation of the UHI

Given that the UHI impacts alteration of city surface-atmosphere energy exchange, air quality, and human health, developing ways to mitigate the UHI are becoming increasingly important to policy- and decision-makers and the general public. There are several ways that actions can be taken to cool urban surfaces, thereby reducing the amount of long wave energy that emanates from urban surfaces to force the UHI. These actions are promoted by the US Environmental Protection Agency as part of its UHI Mitigation initiative (<http://www.epa.gov/heatisland/>) and are increasingly being used by cities around the world in their efforts to reduce urban

Figure 8 A summer thermal image of a tree growing in an asphalt parking lot in Athens, GA. The reduction in asphalt temperature caused by shading is approximately 10 °C. Luvall, NASA, Marshall Space Flight Center.

temperatures. The methods being promoted to mitigate the UHI are

- planting trees and vegetation,
- installing green roofs, and
- installing cool roofs.

Trees, vegetation, and green roofs can reduce the amount of urban surface thermal energy to mitigate the UHI, and can provide other important benefits such as reducing heating and cooling energy use and associated air pollution and greenhouse gas emissions, remove air pollutants, sequester and store carbon, help lower the risk of heat-related illnesses and deaths, improve storm-water control and water quality, reduce noise levels, create habitats, improve aesthetic qualities, and increase property values (Figure 8) (Rosenzweig et al., 2006). Cool

Figure 9 A 70 000 square foot rooftop meadow complete with trees constitutes the green roof of the Mormon Church Mormon Assembly Hall in Salt Lake City, UT. Luvall, NASA, Marshall Space Flight Center.

Figure 10 (a and b) The original black membrane roof in the Energy Solutions Arena, Salt Lake City, UT is 48 °C. The replacement white membrane roof is 28 °C. Luvall, NASA, Marshall Space Flight Center.

roofs, either by installing green (vegetated) roofs or by installing highly reflective roofing material, can reduce thermal energy emittance into the lower atmosphere, and lower cooling energy use, peak electricity demand, air pollution, greenhouse gas emissions, and heat-related incidents that stress the human body (Figure 9).

Rooftops in urban areas, particularly in the CBD where there are many buildings in close proximity to one another, can become extremely hot due to the type of roofing materials used. Black membrane roof temperatures on these roofs can be 75 °C or warmer in the summertime. Even during September and several hours after solar noon, these roofs can get very hot. The Energy Solutions Arena rooftop shown in Figure 10(a) had a temperature of 49 °C on 30 September, at 4.45 p.m. This same roof was in the process of being reroofed with high reflectance material (i.e., high albedo) that significantly lowered its temperature to 28 °C (Figure 10(b)).

Cool pavements are also being used to reduce thermal response from the urban surface. The term currently refers to paving materials that reflect more solar energy, enhance water evaporation, or have been otherwise modified to remain cooler than conventional pavements. Conventional paving materials can reach peak summertime temperatures of 48–67 °C, transferring excess heat to the air above them. Cool pavements can be created with existing paving technologies (such as asphalt and concrete) by increasing the porosity of these surfaces for increased water retention, as well as with newer approaches such as the use of coatings or grass paving.

Diurnal Cycle

A Betts, Atmospheric Research, Pittsford, VT, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The diurnal cycle over land is driven by solar heating in the daytime, and longwave cooling at night. In summer, the maximum temperature decreases with increasing cloud cover, because clouds reflect sunlight. In winter, the minimum temperature falls steeply under clear skies, because clouds reduce the longwave cooling to space. Over moist soils, increased evaporation reduces the diurnal temperature and humidity ranges. A few hours after sunrise, there is a transition when the nighttime stable layer is eroded by surface heating. Carbon dioxide shows a dawn maximum as nighttime respiration is trapped near the surface, and an afternoon minimum.

Introduction

Near the Earth's surface, many variables have a characteristic *diurnal or daily* cycle, driven by the diurnal cycle of the incoming solar radiation, which is zero at night and peaks at local noon. The atmosphere is relatively transparent to the short-wave radiation from the sun and relatively opaque to the thermal radiation from the Earth. As a result, the surface is warmed by a positive net radiation balance in the daytime in summer, and cooled by a negative radiation balance at night. The surface temperature oscillates almost sinusoidally between a minimum at sunrise and a maximum in the afternoon. This is referred to as the diurnal cycle of temperature. In warm seasons, the daily net radiation balance is positive, and the daily mean temperature is determined by the daily mean surface energy balance, which involves not only the short- and long-wave radiation components, but also heat transfers to the atmosphere.

The magnitude of this diurnal range of temperature is determined by many factors, which we shall discuss. Clouds have a large impact on the surface radiation balance and this differs between warm and cold seasons. The nature of the underlying surface is important, whether land or water, and so is the coupling to the atmosphere above. The phase change of water, particularly evaporation and condensation plays an important role in moderating the diurnal range of temperature, because of the large latent heat of vaporization. (In cold climates, the freezing and thawing of the soil are also important on the seasonal timescale.)

Over the ocean (and large lakes), the diurnal temperature range is small, because the incoming solar energy is mixed downward into the ocean 'mixed layer,' which is usually tens of meters deep. One day of solar heating will warm a layer of water 50 m deep to less than 0.1 K, because of its large thermal capacity. Only in light winds, when the downward mixing is small, does the diurnal range of sea surface temperature reach 1 K. On timescales longer than the diurnal, evaporation of water primarily balances the surface net radiation budget.

Over land, only a small fraction (<20%) of the net radiation at the surface is conducted downward in the daytime, or stored by warming trees on the surface, for example. As a result, the surface temperature rises rapidly after sunrise, until near balance is achieved between the net radiation and the direct

transport of heat to the atmosphere (referred to as the *sensible heat flux*) and evaporation of water (or transpiration from plants), referred to as the *latent heat flux*. If the surface is a desert, then the daytime temperature rise is large, but if water is readily available for transpiration, the daytime rise of temperature is greatly reduced, because most of the net radiation goes into the latent heat of vaporization. The surface sensible and latent heat fluxes have a large diurnal cycle, with a peak near local noon, as they are driven primarily by the incoming solar radiation. The surface temperature peaks a little later in the afternoon, when the surface sensible heat flux goes negative as the surface cools.

Coupling of the Summer and Winter Diurnal Cycle to Clouds

The diurnal cycle over land is driven by the surface net radiation balance, which we may write

$$R_n = SW_n + LW_n \quad [1]$$

where the net radiation, R_n , is the sum of the net shortwave radiation, SW_n a heating term, and the net longwave radiation, LW_n a cooling term. The net shortwave flux is reduced by reflection at the surface, which we call the surface albedo, α_s ; and by the reflection and absorption by the cloud fields above, which we call the effective cloud albedo (ECA). So we can write the reduction of the downward clear-sky flux, $SW_{dn}(\text{clear})$ in the form

$$SW_n = (1 - \alpha_s)(1 - \text{ECA})SW_{dn}(\text{clear}) \quad [2]$$

Grassland or crops have α_s in the range 0.15–0.2, but this rises to 0.6–0.8 with snow cover. The boreal forest has a lower α_s of order 0.1, and this rises to about 0.4–0.5 with snow on the canopy, and falls back to 0.2 once the canopy sheds the snow. This is because snow on the ground is largely in the shade of the trees. The ECA has an even wider range: zero with a clear sky by definition, and >0.9 in overcast conditions with heavy rain. So cloud cover is an important modulator of the diurnal cycle. We will illustrate this using Canadian Prairie data, which have long-term records of opaque or reflective cloud cover that have been calibrated to the ECA.

Figure 1(a) shows that in summer (June–July–August) the amplitude of the diurnal cycle increases as daily mean opaque cloud cover falls from 95 to 5%. In summer, near-surface temperature is minimum at sunrise, but this falls only slightly when cloud cover is small. On the other hand, the afternoon temperature maximum increases steeply as cloud cover decreases, and SW_n increases. Cooled by the net outgoing longwave radiation, LW_n , the surface temperature falls at night from the afternoon maximum back to the sunrise minimum.

Figure 1(b) shows an inverted pattern for winter (December–January–February): it is coolest with near-clear-sky conditions. This shows that there are fundamental differences between the surface radiation balance with clouds between summer and winter. The sun is low in the sky in winter, and the Prairies have a high surface albedo with snow, so SW_n in eqns [1] and [2] becomes small. However, clouds also blanket the Earth and greatly reduce LW_n , the surface cooling to space, and this longwave effect of clouds becomes dominant in winter. We see that the diurnal range of temperature is very small with 95% cloud cover. As cloud cover decreases, the surface cooling increases and the temperature drops. The minimum temperature at sunrise falls the most, because in the daytime the LW_n cooling is partly offset by SW_n heating.

Figure 1 Dependence of diurnal cycle of temperature on opaque cloud cover in (a) summer and (b) winter for Regina, Saskatchewan, Canada.

Dependence of Diurnal Cycle on Evaporation

Figure 2 illustrates this diurnal variation using data from sunny days in midsummer during a 1987 field experiment (with acronym FIFE) conducted over grassland near Manhattan, Kansas. The panels on the left (from top to bottom) show net radiation, R_n , sensible heat flux, H , and latent heat flux, LE . The surface energy balance can be written as

$$R_n = H + LE + G \quad [3]$$

where G is the storage in the ground and vegetation, which we do not show. In addition a small amount of energy goes into photosynthesis, which again we do not show. The time axis is local solar time, which is UTC-6 h. The data have been grouped and averaged based on the percent soil moisture (SM) in the first 10 cm of soil, so that there are three curves (each an average of about 10 days) representing dry, medium, and wet soils. The upper left panel shows that the mean net radiation on these sunny days is very similar. However because SM is a major control on evaporation, the partition of the net radiation into sensible and latent heat is very different. When the soil is wet, the latent heat flux (or 'evaporative energy' flux) is about three times the sensible heat flux, whereas when the soil is dry, these two fluxes are nearly equal. The panels on the right side show the response to the different surface forcing. The upper right panel shows the surface temperature (measured by an infrared radiation thermometer, mounted on a tower and pointed downward at the grass). Although R_n is the same, on days when the soil is dry and water is not readily available for evaporation, the surface gets very hot, as warm as 44 °C near noon. This warm surface temperature drives the large sensible heat flux H and heats the air above the surface. The diurnal range of the surface temperature is more than 20 °C on these days, while for the air at 2 m above the surface in the middle panel, the diurnal range is only 12 °C. As SM increases, the daily maximum surface and air temperature decrease. The upper two panels on the right are similar, except that the amplitude of the surface temperature is larger than that of the air temperature. Both are related to the sensible heat flux H . Note that the air temperature has a broad afternoon maximum, because H is upward as long as the surface is warmer than the air. The surface temperature falls below the air temperature only in late afternoon, H then changes sign, and at night the surface is cooler than the air. The lower right panel shows the diurnal cycle of relative humidity (RH) as a percentage. Over the wetter soils, the RH of the air at 2 m reaches 85% before sunrise, and falls in the daytime as the surface and air warm. The fall of RH is smallest on the days with the greatest evaporation, LE . When evaporation is reduced because the soil is dry, daytime RH falls as low as 30% and even at night, only reaches 72% at sunrise.

Coupling between the Surface Diurnal Cycle and the Atmospheric Mixed Layer

As the land surface is heated during the daytime, a dry convective boundary layer grows in depth. This is called the

Figure 2 Diurnal cycle of net radiation (R_n), sensible heat flux (H), and latent heat flux (LE) (a–c); surface temperature, air temperature, and RH (d–f), stratified by percent volumetric SM in first 10 cm of the soil.

‘mixed layer,’ because the turbulent dry convection rapidly stirs the layer to one of near-neutral buoyancy and near-constant water vapor mixing ratio. The diurnal cycle of the surface and the mixed layer are tightly coupled. As a result the pre-existing atmospheric structure above the surface at sunrise has a considerable impact on the daytime diurnal cycle, as illustrated in the following figures using surface and sounding data collected over the boreal forest in Saskatchewan, Canada during the Boreal Ecosystem-Atmosphere Study (BOREAS) in 1994. **Figure 3** shows the surface diurnal cycle for 2 days in spring. The upper panel shows for each day the temperature at two levels, an upper level T_U , which is at 21 m, about 5 m above the canopy of a jack pine forest, and a lower level about 5 m above the forest floor. On both days the surface cools strongly at night and rises steeply after sunrise with a greater diurnal range than the near-clear-sky case in **Figure 1**. The diurnal range under the canopy is larger than above it. At night on 26 May, the winds are lighter, and the near-surface nighttime boundary

layer is more stable (see **Figure 4**). The air under the canopy becomes effectively decoupled from the atmosphere above and the stable temperature gradient across the canopy at night reaches 7 K. There is very little evaporation from either the forest, or the cold lakes at this time in spring. The lower panel shows RH measurements above the canopy. In the late afternoon, RH falls as low as 20% on 31 May. Before sunrise on this day, RH above the canopy reaches 90% as T_U falls to a minimum of 4 °C. RH was not measured below the canopy, but the temperatures there are cold enough to saturate the air in the hours before sunrise. The dew point is often used to estimate minimum nighttime temperatures at the surface.

The right-hand scale of the upper panel shows the corresponding dry potential temperature, which is defined as

$$\theta = (T + 273.15)(1000/p)^{.286} \quad [4]$$

where p is the surface pressure (here about 950 hPa, since the observation site is about 500 m above sea level). The potential

Figure 3 Diurnal cycle of temperature, above and below a boreal forest canopy (a), and of RH above the canopy (b) for 2 days in May 1994.

temperature, θ , is useful as a variable because it allows us to compare the surface and atmosphere above. During the daytime the boundary layer above the surface is mixed to almost constant potential temperature (see Figure 4). The strong radiative cooling of the surface at night generates a stable layer close to the ground, typically only a few hundred meters deep. About 3–4 h after sunrise, the surface has warmed enough to remove this stable surface layer and reconnect to a deeper layer. When this happens, the rate of rise of temperature and the rate of fall of RH decrease sharply. In Figure 3, this occurs on 26 May at a local time of 8.8 h, when θ reaches 296 K; while on 31 May, it occurs at 7.8 h, when $\theta = 289$ K, and on this day the change is smaller.

Figure 4 shows sequences of seven profiles of potential temperature in the lower troposphere, measured by rawinsonde ascents, nominally every 2 h from sunrise to late afternoon on the 2 days. The upper panel shows at sunrise (417 LST, solid) a cold (stable) surface layer only about 25 hPa deep (200 m), with a deep layer above of constant θ , which is the residual or ‘fossil’ mixed layer from the previous

Figure 4 Profiles of potential temperature in the lower troposphere on (a) 26 May and (b) 31 May.

day. At the surface the temperature warms rapidly, as the surface sensible heat flux is trapped in this shallow surface layer. The profile at 0824 LST shows a mixed layer with $\theta = 294.5$ K to 890 hPa. Shortly afterward, when the surface potential temperature reaches $\theta = 296$ K, the new growing boundary layer merges with the deep residual mixed layer. From then on, the surface and mixed layer warm much more slowly, as seen in Figure 3. Even though H exceeds 300 W m^{-2} at all the forest sites for several hours around local noon (not shown), this large heat flux is distributed through a deep layer.

The lower panel shows the time sequence on 31 May. Note that at sunrise (solid), the profile is quite different than on 26 May. Instead of a deep layer of constant θ , produced by dry convection the previous day (a so-called dry adiabatic structure), there is a layer from 920 to 650 hPa in which

Figure 5 Monthly mean diurnal cycle of CO_2 for June, August, and October for a boreal jack pine site. Data from McCaughey, J.H., Dr., Queens University, Kingston, Ontario.

θ increases steadily with height. In fact, this layer was produced by showers the previous evening (and it has a so-called wet adiabatic structure). The change in slope of the early morning profile at 920 hPa is at $\theta = 289$ K, and hence we see on [Figure 3](#), a change in the rate of warming, once the surface reaches this potential temperature. This change of slope is more dramatic on 26 May, because the change in the vertical profile is also greater. On 31 May, the mixed layer grows steadily all day until it is 300 hPa deep (about 3000 m) in the late afternoon. On both these days, there is some broken cumulus cover in the afternoon at the top of the mixed layer. The rapid warming on 31 May, that is seen between 500 and 600 hPa, is related to the lowering and change in structure of a powerful jet stream above, not by surface processes.

Diurnal Cycle of CO_2

The diurnal cycle of the solar radiation drives a diurnal cycle in CO_2 through photosynthesis and respiration in plants. [Figure 5](#)

shows the mean diurnal cycle over a young jack pine canopy (about 5–6 m tall) near Thompson, Manitoba from the 1996 BOREAS experiment for 3 months, June, August, and October. During the summer months, CO_2 decreases during the daylight hours as it is taken up in photosynthesis, and increases at night as it is released by respiration from both plants and soil. The amplitude of the diurnal cycle increases from June to August, but the monthly mean decreases as there is a net CO_2 uptake by the entire Northern Hemisphere. By October of this year however the diurnal cycle is very small, as temperatures have dropped low enough that both photosynthesis and respiration have almost ceased.

Synopsis

The basic concepts of order, molecularity, rate coefficient, and the temperature dependence of rate are presented first, before turning to theoretical interpretations of rates of bimolecular reactions in the gas phase such as collision theory and transition-state theory. The modifications needed when long-range forces operate, as in ion–molecule reactions, are indicated. Unimolecular and termolecular reactions may occur via discrete steps, which can often be treated kinetically using the stationary-state hypothesis. The dependence of rate on pressure (and temperature) may be complex. Consideration is given in the last section to the kinetics of processes occurring on and within water droplets and other atmospheric aerosol particles.

Reaction Kinetics and Atmospheric Chemistry

Chemistry in the atmosphere often consists of several consecutive and parallel steps that compete with each other. Interpretation of the rates of chemical change, and the concentrations and lifetimes of atmospheric constituents, requires a knowledge of the rates of the *elementary* reaction steps that make up the complex scheme. The *kinetic data* embodied in this knowledge are best obtained by laboratory experiment, although theory may have to be used if the experiments cannot be performed. Theory is useful in another way as well, because it can provide a rational basis for the extrapolation of laboratory data to temperatures, pressures,

and concentrations that exist in the atmosphere, but that cannot be used in the laboratory studies.

Rate Laws

Consider the hypothetical chemical reaction

Experimentally, the rate is found to be proportional to the concentrations of A, B, ... raised to some power

$$\text{Rate} = -\frac{d[A]}{dt} = -\frac{d[B]}{dt} = k[A]^\alpha[B]^\beta \quad [1]$$

Order, Molecularity, and Rate Constant

The powers α and β are the *order* of reaction with respect to reactants A and B, and $\alpha + \beta$ is the overall order; the constant of proportionality, k , is the *rate coefficient* (rate 'constant'). The *molecularity* of a reaction is the number of reactant molecules written in the stoichiometric equation. Order is thus an experimental quantity, molecularity an arbitrary theoretical one. An elementary reaction step is conceived as one that cannot be split into any chemically simpler processes. For truly elementary steps, order and molecularity are in general identical. Thus, if [reaction \[1\]](#) is elementary, and the only reactants are A and B, it is both bimolecular and overall second-order: first-order in each of the components A and B. However, a special case often arises in atmospheric chemistry. If the second reactant, B, is in great excess over A, then its concentration is effectively constant throughout the reaction. We can then combine the concentration with the rate coefficient, k , and write the rate of reaction as $k'[A]$, where $k' = k[B]$. Such a process is termed a *pseudo-first order* reaction, and k' is the *pseudo-first order rate coefficient*.

The Arrhenius Equation

Many rate constants are found to follow a temperature law embodied in the *Arrhenius expression*

$$k = A \exp\left(-\frac{E_a}{RT}\right) \quad [2]$$

where E_a is the *activation energy* and A is the *preexponential factor*. The Arrhenius equation is entirely empirical, but several theories of kinetics yield expressions for the rate coefficient that are similar in form.

Theories of Elementary Gas-Phase Bimolecular Reaction Steps

Bimolecular processes are probably the most important class of reaction, and, as we shall see later, termolecular, and many very important unimolecular, reactions involve several bimolecular elementary steps. The obvious starting point in discussing the theories of reaction is thus with bimolecular reactions. Two simplifications are commonly adopted in discussions of these theories. The first is the *collision theory* (CT), and the second *transition-state theory* (TST).

Collision Theory

In simple CT, reactant molecules are assumed to be hard spheres (radii r_A and r_{BC} in our example), and reaction is taken to be possible only if two conditions are met: a collision must occur, and the energy of collision along the line of centres must equal or exceed the energy required, E_c , to reach a critical configuration ($ABC^\ddagger$ in Figure 1 in *Chemistry of the Atmosphere: Principles of Chemical Change*). The rate of reaction according to this theory is readily shown to be given by

$$-\frac{dn_A}{dt} = -\frac{dn_{BC}}{dt} = n_A n_{BC} \sigma_c \bar{c} \exp\left(-\frac{E_c}{RT}\right) \quad [3]$$

where σ_c is the *cross-sectional area* (or *collision cross-section*)

$$\sigma_c = \pi(r_A + r_{BC})^2 \quad [4]$$

and $\bar{c}$ is the mean relative speed of molecules for temperature T ,

$$\bar{c} = \left(\frac{8k_B T}{\pi \mu}\right)^{1/2}; \quad \mu = \frac{m_A m_{BC}}{m_A + m_{BC}} \quad [5]$$

The quantities n_A and n_{BC} are the *number densities* of A and BC (concentrations in molecular units such as molecule cm^{-3}), respectively. [Equation \[3\]](#) certainly has the correct concentration dependence for an elementary bimolecular reaction, so that the rate coefficient can be written as:

$$k = \sigma_c \bar{c} \exp\left(-\frac{E_c}{RT}\right) \quad [6]$$

It is clear that the Arrhenius equation ([eqn \[2\]](#)) and [eqn \[6\]](#) closely resemble each other, and E_c is commonly identified with E_a , so that the question may be asked if $\sigma_c \bar{c}$ is to be compared with A . However, it should not be forgotten that $\bar{c}$ is dependent on $T^{1/2}$ (cf [eqn \[5\]](#)), while A , in the simplest formulation, is not temperature dependent. A more telling difficulty concerns the absolute magnitudes of A and $\sigma_c \bar{c}$. For typical atmospheric reactants, with collision radii ~ 400 pm and relative molecular masses ~ 30 , $\sigma_c \bar{c}$ is $\sim 3 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 300 K. The product $\sigma_c \bar{c}$ is called the *collision frequency factor*. Except for the very simplest of reactants, experimental A factors are usually less than, and often much less than, the collision frequency factor. An explanation for the lack of agreement is sought in terms of molecular complexity, with the existence of special geometric arrangements that are needed during the collision to bring reactive parts of the molecules together (*steric requirements*), and of special needs for the distribution of internal energy. That explanation takes us well away from the idea of hard-sphere reactants.

Transition-State Theory

The alternative simplification adopted in the interpretation of bimolecular reactions is that of the TST or *Activated Complex Theory* (ACT). The reactants and the critically configured ABC molecule are assumed to be in 'quasi-equilibrium.' Equilibrium constants can be expressed in statistical thermodynamic terms, and if the formulation is also valid for the quasi-equilibrium, where the system is at a (free) energy maximum rather than minimum, then concentrations of $ABC^\ddagger$ (the *transition state*) may be calculated. Rates of reaction can then be obtained from the rate at which $ABC^\ddagger$ passes to products (as a result of translational or vibrational motions along the reaction coordinate). The resultant rate coefficient, k , is given by

$$k = \frac{k_B T}{h} \frac{q''_{ABC^\ddagger}}{q'_A q'_{BC}} \exp\left(-\frac{E_c}{RT}\right) \quad [7]$$

Partition functions are written as q'_A , q'_{BC} , $q''_{ABC^\ddagger}$ for reactants and transition state, the primes showing that the quantities are volume independent. The double prime on $q''_{ABC^\ddagger}$ indicates that the motion along the reaction coordinate has been factorized out (and a numerical constant introduced). In TST, then, the internal motions neglected in CT are expressly taken into

account through the use of the partition functions. TST concentrates only on that region of the potential energy surface around the transition state (for the calculation of the partition function $q''_{ABC^\ddagger}$) while CT is interested only in the height of the energy barrier at the transition state. It is the calculation of $q''_{ABC^\ddagger}$ that offers most difficulty in the practical implementation of TST. Spectroscopic parameters for the reactant molecules are usually available, so that q'_A and q'_{BC} are readily estimated. However, a knowledge of the shape of, and the forces acting at, the transition state would imply that the potential energy surface is itself known, at least in the region of $ABC^\ddagger$. The usual practice is to make an 'informed guess' at the magnitude of $q''_{ABC^\ddagger}$ based on a hypothetical interaction mechanism and a corresponding model for the transition state. Considerable differences in predicted preexponential factors are obtained from models of the transition state that are, for example, linear, bent, or cyclic. In a more limited way, TST can suggest a sensible order of magnitude for the preexponential factor. The three total partition functions in eqn [7] are each the product of translational, rotational, and vibrational partition functions. The translational parts can all be calculated, and orders of magnitude for rotational and vibrational parts employed in accordance with the number of each of these modes that exist in A, BC, and $ABC^\ddagger$. The temperature dependence for every partition function can be evaluated as a power law, so that eqn [7] can be rewritten as

$$k = A'T^n \exp\left(-\frac{E_c}{RT}\right) \quad [8]$$

where A' is the temperature-independent part of the preexponential factor, and n some exponent chosen from the nature of the reactants (monatomic, diatomic, etc.) and a model of the transition state. For the hard sphere (CT) case, $n = 0.5$, from eqns [2] and [4]. In the more general case, n can be positive or negative. The most sensible procedure in temperature extrapolation thus seems to be first to predict n from a model of the reaction, and then to fit the experimental data to eqn [8] with that value of n .

Activation Energies and Long-Range Forces

Rates of reaction are, in part, controlled by the energy of a critical (transition-state) configuration, an energy that has as its counterpart the activation energy of experimental kinetics. The energy barrier arises because the reactant molecules are forced close together (closer than the sum of their radii in the hard-sphere collision approximation), and reactant bonds have to be broken while product bonds are made. The energy required is less than that required first to break reactant bonds and then to form product molecules in separate steps. The energy does not decrease at any stage in this picture as the system passes from separated reactants to the transition state. Such a decrease in energy would correspond to long-range attractive forces, and might lead to an increased collision frequency, and to an A factor that exceeded $\sigma_c \bar{c}$. Many examples of this type of behaviour are in fact known, even with neutral reactants, but the effects are strongest and most common with charged reactants. In *ion-molecule* reactions, such as

the ion can induce a dipole in the neutral reactant, and the resultant attractive force can both balance the ordinary chemical activation barrier as well as make the real encounter rate greater than the gas-kinetic collision frequency factor for neutral molecules. Near-zero activation energies are thus often found in this type of reaction, and the preexponential factors (typically $\sim 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) are several times larger than the values for neutral reactants. Because the long-range attractive forces dominate the potential energy, high velocities of approach are counterproductive in promoting reaction, and some *negative temperature coefficient* of rate constant may be observed. The stronger (or longer range) the interaction, the larger the rate coefficient. For ion reactions with neutral molecules possessing permanent (rather than induced) dipoles, preexponential factors are increased by another two or three times. Thus, charge transfer from O^+ to the dipolar molecule H_2O ,

has a rate coefficient of $2.3 \times 10^{-9} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ at 298 K, and the activation energy is essentially zero. The long-range interactions are yet larger, of course, for two reactants both of which are charged. Positive ion-negative ion, or positive ion-electron reactions are characterized by rate coefficients three to four orders of magnitude larger than typical gas-kinetic collision frequency factors. For example, the rate coefficient (298 K) for neutralization of NO^+ by an electron

is $4.5 \times 10^{-7} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$.

Multistep Reactions and the Stationary-State Hypothesis

Atmospheric chemistry consists of complex interactions of elementary reactions. Some of the processes to be described in the section that follows on unimolecular and termolecular reactions also involve several steps, which is why the subject of multistep reactions is introduced at this stage.

Consecutive and *parallel* steps involve reactive *intermediates* in competitive processes. Reaction intermediates of particular interest include atoms, radicals, ions, and excited species. Most of these intermediates are highly reactive, and, with one or two exceptions, cannot be 'stored' in a laboratory for long periods because they are lost on the walls of the containing vessel, or react with each other. Such intermediates are not necessarily *unstable*, and chemical lifetimes of isolated atoms or radicals in the absence of surfaces can be virtually infinite. Many excited-state species are unstable, since they may possess enough internal energy to fragment, and they may also be able to lose their energy by emission of radiation. An excited species that cannot undergo loss by an allowed radiative transition is said to be *metastable*.

Multistep reaction schemes are interpreted kinetically by writing down the differential equations, such as eqn [1], for all the species of interest, including the intermediates. Solution of these equations then allows prediction of the concentration-time variation of each of the species. Unfortunately, analytical solution of the many simultaneous differential equations is rarely possible. Numerical solution has become a widely

used alternative since the advent of high-speed computers and the development of good techniques for dealing with differential equations. For some highly reactive intermediates, the *Stationary-State Hypothesis* (SSH) (often alternatively called the *Steady-State Hypothesis*) provides a simplification that will permit algebraic solution of the kinetic equations. Consider an intermediate X that is created in a process whose rate is constant, and whose loss rate increases with increased [X]. After the reaction is started, [X] will increase until the rate of loss is equal to the rate of formation. A steady state for [X] has been reached, and $d[X]/dt \rightarrow 0$. To illustrate the stationary-state method, consider the pair of reactions

For simplicity, let [B] and [C] be in great excess, so that we may write pseudo-first-order rate coefficients $k'_f = k_f[B]$ and $k'_t = k_t[C]$. The kinetic equation that describes reactions [V] and [VI] is

$$\frac{d[X]}{dt} = k'_f[A] - k'_t[X] \quad [9]$$

If X is in a stationary state, then we set the differential equal to zero, and

$$[X]_{ss} = \frac{k'_f[A]}{k'_t} \quad [10]$$

where $[X]_{ss}$ indicates a steady-state concentration of X. The problem is to know if the concentration of X calculated using the SSH bears any relationship to actual concentrations. Our two-reaction example has been chosen because it can also be solved analytically. So long as [A] and [C] are independent of time, eqn [9] can be integrated to yield

$$[X] = \frac{k'_f[A]}{k'_t} [1 - \exp(-k'_t t)] \quad [11]$$

where t is the time for which the system has been reacting. This expression for [X] approaches the steady-state expression so long as $k'_t t \gg 1$, the error in applying the SSH being less than 1% for $k'_t t > 4.6$. The SSH can thus be applied so long as [A] and [C] remain constant over a period long enough for this inequality to be reached. It is evident that the circumstances under which the SSH is most likely to be valid are thus those where $k'_t t$ is large: that is, if the species X is highly reactive. One example of a species at steady state in the atmosphere is the highly reactive electronically excited state of atomic oxygen, $O(^1D)$, throughout the troposphere, stratosphere, and probably the mesosphere. Ground-state atomic oxygen, $O(^3P)$, however, cannot generally be treated in the atmosphere by steady-state methods because of its relatively small reactivity.

Theories of Unimolecular and Termolecular Reactions

We are now in a position to consider thermal unimolecular reactions, and their close counterpart, termolecular reactions. If chemical reaction requires collision between, or at least close proximity of, the reactants, then it might seem that all thermal processes ought to be kinetically of second order.

Unimolecular, first-order, elementary processes appear to lack the necessary approach of reactants, and termolecular, third-order, steps suffer from the impossibility of a simultaneous collision between three hard-sphere reactants. The explanation for first- and third-order thermal kinetics shares common ground, and a simple introduction is provided here.

No obstacle exists to understanding how single-step unimolecular and first-order decomposition occurs in a molecule AB that *already* has more than enough energy in it to break one of its bonds. An obvious case is the photodissociation of polyatomic molecules, where optical dissociation or predissociation populates vibrational levels of AB sufficient to cause fragmentation (see **Chemistry of the Atmosphere: Principles of Chemical Change**). The rate of fragmentation may depend on the rate at which energy can accumulate in the bond to be broken, but the reaction will be kinetically of first order. *Chemical activation* offers another route to high vibrational excitation. For example, the reaction of HO_2 with NO can produce a highly excited $HO_2NO^\dagger$ molecule (the dagger representing vibrational excitation)

This excited $HO_2NO^\dagger$ can then either split up to the reactants again, or form OH and NO_2

Reaction of the excited $HO_2NO^\dagger$ is an unimolecular, first-order, elementary reaction.

It is in interpreting *thermal* unimolecular reactions that some difficulty arises, since the formation of an excited $AB^\dagger$ molecule involves collisions between the AB species, and might therefore be expected to show *second-order* kinetics. A basic understanding was provided by Lindemann, who suggested that thermal first-order reactions were not true elementary steps, but rather involved at least three elementary processes:

If reaction [X] dominates over [XI] as a loss process for $AB^\dagger$, then the concentration of $AB^\dagger$ is almost at its thermal equilibrium value, while the rate-determining step for reaction is the first-order process [XI]. Overall first-order kinetics follow. It is obvious, however, that at sufficiently low concentrations of AB, there becomes a point at which reaction [IX] is rate limiting, and the kinetic behaviour will be second order. Transition from first- to second-order behaviour is, indeed, seen at low enough pressures in this kind of thermal unimolecular reaction. Quantitative expression of these ideas can be obtained by a steady-state treatment for the concentration of $AB^\dagger$ as described in the previous section. The result for the rate of loss of AB is

$$-\frac{d[AB]}{dt} = k_1[AB] = \frac{k_a k_r [AB]^2}{k_d [AB] + k_r} \quad [12]$$

where k_1 is the experimentally defined pseudo-first order rate coefficient. So long as $k_d [AB] \gg k_r$, the reaction is first order, but if [AB] is reduced to the point at which the reverse inequality

holds, then the reaction becomes second order. At high concentration, the limiting value of k_1 (referred to as k_1^∞) is equal to $(k_a k_t / k_d)$ and is thus truly first order, being independent of $[AB]$. The low-pressure limit, k_1^0 , is equal to $k_a [AB]$ and is itself first order in pressure, or second order overall.

Considerations about high- and low-pressure extrapolations of rate data are most frequently met in atmospheric chemistry in connection with termolecular reactions. As with unimolecular reactions, termolecular processes have orders variable with pressure, being third order at 'low' pressure and second order at 'high' pressure. Such reactions are extremely important in combination processes (sometimes erroneously called 'recombination' processes), and we can see why by first looking at the reaction of two atoms to form a diatomic molecule. A typical case is the combination of two $O(^3P)$ atoms. Curve 'X' in Figure 2 of Chemistry of the Atmosphere: Principles of Chemical Change illustrates this combination. Even if the combining atoms have no relative translational energy, the newly formed O_2 molecule has the $O + O$ combination energy stored in it: that energy is the $O-O$ bond energy, and the O_2 is chemically activated $O_2^\dagger$ at its dissociation limit. Unless some energy is removed within one vibrational period, the molecule will fall apart again as the internuclear distance increases on the first oscillation. Energy can be removed in collisions; the species that dissipates energy is often represented by the symbol M . In the atmosphere of Earth, M is usually the 'bath' mixture of N_2 and O_2 . The overall reaction is now written

which is a termolecular step. The redissociation that has been prevented is the unimolecular dissociation of $O_2^\dagger$ equivalent to step [XI], and the process deactivating $O_2^\dagger$ is the equivalent of [X]. We shall see shortly that internal energy seems to flow fairly freely between different vibrational modes of a polyatomic molecule. If the newly formed molecule is larger than diatomic, there are such modes into which the bond-combination energy can flow. The lifetime of the newly formed molecule can thus correspond to many vibrational periods before the energy flows back to the critical bond. With a large enough polyatomic molecule, the lifetime can be so great that collisional removal of excess energy (*stabilization*) is no longer rate determining, and combination then exhibits second-order kinetics. Because reactions [X] and [XI] are common to both unimolecular and termolecular reactions, the same general considerations about flow of energy apply to both types of process.

The analogue of expression [12] can be derived from the single excitation level kinetic scheme

The result is

$$-\frac{d[AB]}{dt} = k_{II}[A][B] = \frac{k_a k_s [A][B][M]}{k_s [M] + k_t} \quad [13]$$

where k_{II} is the experimentally defined pseudo-second order rate coefficient (analogous to k_1 in eqn [12]). We see straightaway that, if $k_t \gg k_s [M]$, the reaction is third order, with $k_{II}^0 = (k_a k_s / k_t) [M]$. If, however, $k_t \ll k_s [M]$, then the reaction is second order, with $k_{II}^\infty = k_a$. Increased complexity in the molecule AB reduces the value of k_t , because the combination energy is distributed among more vibrational modes. The concentration, or pressure, of third-body M at which third-order behaviour turns over to second-order kinetics is thus lower the more complex the molecule produced. 'Complex' is only a relative term here: combination of two hydrogen atoms to form H_2 is third order up to 10^4 atm, while combination of two CH_3 radicals to form C_2H_6 is second order at all but the lowest pressures. However, it so happens that the reactants in several combination reactions of great atmospheric importance, such as

are of just that molecular size that complex intermediate-order kinetics are displayed at some point in the atmospheric pressure range.

Expressions [12] and [13] represent the variations of experimentally determined rates of reaction with pressure. The pseudo-first- or second-order rate coefficients k_1 or k_{II} can be conveniently expressed in terms of the high- and low-pressure limiting values k_1^∞ , k_1^0 , or k_{II}^∞ , k_{II}^0 . For example, k_{II} in eqn [13] can be expressed as

$$k_{II} = \frac{k_{II}^0 k_{II}^\infty}{k_{II}^0 + k_{II}^\infty} \quad [14]$$

Remembering that k_{II}^0 is itself first order in pressure, it can be seen that eqn [14] represents in outline the variation of k_{II} with pressure that is found experimentally. Figure 1 shows

Figure 1 Rate coefficient for the reaction $OH + NO_2 + N_2 \rightarrow$ products as a function of pressure at $T = 298$ K. Experimental data measured by D'Ottone, L., Campuzano-Jost, P., Bauer, D., Hynes, A.J., 2001. A pulsed laser-photolysis-pulsed laser-induced fluorescence study of the kinetics of the gas-phase reaction of OH with NO_2 . J. Phys. Chem. A 105, 10538–10543.

experimental data for reaction [XVI] obtained over the pressure range 30–700 Torr with $M = N_2$. The ordinate is k_{II} as defined by the first two terms of eqn [13]. At the lowest pressures, k_{II} is seen to be a nearly (but not quite) linear function of pressure, as predicted by the right-hand term of the equation, with the slope corresponding to k_{II}^0 . At higher pressures, k_{II} becomes progressively less pressure-dependent, again as predicted by eqn [13] or eqn [14]. Unfortunately, however, eqn [14] does not match experimental data in detail, so that it cannot be applied directly to the calculation of rates at intermediate pressures. The reasons for the failure are known. The reactions and the rate coefficients k_a or k_c , k_d or k_s , and k_r should have been defined for each individual quantized vibrational level of $AB^\ddagger$, and the individual rates summed to give the total rate. It is, perhaps, easy to see that the more energy available (beyond the critical amount needed to break a particular bond), the more rapid will be the fragmentation (i.e., the larger will be k_r). Related to this point is the implication that energy stored in any vibrational mode can be made available to the critical bond. Experimental evidence largely favours the flow of energy between modes as being fairly free, and the distribution as being near statistical. An additional complication involves the interconversions of vibrations and rotations in the fragmenting molecule. The theory has been extended, modified, and manipulated over the years by Rice, Ramsperger, Kassel, and Marcus, and the familiar initials RRKM are used to designate their formulation. With sufficient sophistication of the input information, very good agreement can be obtained between theory and experiment. Correspondingly, one could have confidence in the extrapolation of data obtained in an intermediate concentration regime to either high-pressure (first-order) or low-pressure (second-order) limits. However, application of RRKM theory to real processes of atmospheric importance is in practice rather difficult, and an alternative, much simpler, approach is now almost universally adopted. This approach has its origins in work by Troe on the theoretical prediction of unimolecular reaction rate parameters. However, with k_{II}^∞ , k_{II}^0 known, Troe has shown that a simplification of his theory allows the right-hand side of eqn [14] to be multiplied by a broadening factor, F , that is a function of (k_{II}^0/k_{II}^∞) . For many atmospherically important termolecular reactions F may be calculated from a simple mathematical expression

$$F = F_{\text{cent}}^{\{1 + [\log_{10}(k_{II}^0/k_{II}^\infty)]^2\}^{-1}} \quad [15]$$

where F_{cent} is the broadening factor for the centre of the fall-off curve; typically, $F_{\text{cent}} = 0.6$.

Third-order reactions often show decreasing rate with increasing temperature: they have a *negative temperature coefficient*. The reason is that the larger the thermal kinetic energy possessed by the reactants A and B in process [XIII], the more internal vibrational energy will be stored in the $AB^\ddagger$ molecule produced. As pointed out earlier, the chance of the critical bond energy finding its way back to a breakable bond is thus increased, and k_r is larger. Since k_c and k_s are only slightly affected by temperature, it follows from eqn [13] that the rate of reaction will decrease with increasing temperature. Thermal energy in effect assists the newly formed molecule to split up again, thus slowing the rate of combination. In the third-order limit, k_{II}^0 is inversely proportional to k_r (see above). Theory

suggests that the temperature variations of k_r should be better expressed in terms of a power, T^n , rather than as a conventional activation energy. Hence, experimental measurements of k_{II}^0 as a function of temperature should be fitted against a T^{-n} law to allow rational interpolation or extrapolation to atmospheric temperatures. Typical measured values of n are 2.5–3.1 for reaction [XVI] and 1.7 for reaction [XVII]. Models of the transition state for bond-association reactions also suggest that, at the high-pressure limit, k_{II} should possess a negative exponent of temperature.

Condensed-Phase, Surface, and Heterogeneous Reactions

Reactions within the liquid droplets of clouds and fogs are important in several aspects of tropospheric chemistry, such as the oxidation of sulfur dioxide. Liquid or solid particles can play a critical role in the chemistry of the stratosphere under certain conditions. Particles such as those of sulfate aerosol or clouds formed from water-ice and hydrates of nitric acid (*polar stratospheric clouds*, PSCs) are implicated in such processes. This chemistry may involve surface reactions, or reactions within the bulk material, but the interface between gas and condensed phases is involved in some way, and the reactions are thus known as *heterogeneous reactions*. The types of heterogeneous process that are found in the atmosphere are considered in more detail in article **Chemistry of the Atmosphere: Principles of Chemical Change**.

The possible complexity of the kinetics can be illustrated by considering explicitly the steps involved in a heterogeneous reaction of a gas-phase species with either the bulk constituent of a liquid droplet or with another species that is already dissolved in it. The uptake of gas-phase molecules can be either reactive or nonreactive. Chemical change corresponds to loss of the gas-phase molecule; uptake that is nonreactive can arise from physical dissolution or from reversible chemistry. Figure 2 illustrates some of the most important individual steps that can be envisaged in a reaction where at least one of the reactants and one of the products is a gas-phase species, but where the chemistry takes place within a droplet. The forward steps shown in the diagram are (1) gas-phase transport of the reactant to the surface of the droplet; (2) accommodation at the surface; (3) diffusion into the liquid; (4) chemical reaction; (5) diffusion of both products and unreacted molecules to the surface; and (6) desorption of species from the interface. Characterization of each of these individual steps is obviously a formidable task, although one that may be simplified – as often happens in kinetics – by one of the steps being rate-determining.

In many respects, the kinetics of liquid, surface, and heterogeneous reactions are governed by the same principles that we have established for gas-phase processes. There are, however, some key differences. Reactions occurring *inside* particles are really confined to the liquid phase, since diffusion coefficients within solids are too small to allow significant reaction rates. On the other hand, reactions *on* solid surfaces are thought to be of very considerable atmospheric significance. The PSCs involved in stratospheric chemistry consist, for example, in part, of solid water-ice and solid nitric acid

Figure 2 Processes involved in the uptake and chemical reaction of a gas-phase molecule by a liquid droplet, and chemical reaction within it. The individual steps are explained in the text. Diagram based on an idea of Ravishankara, A.R., 1997. Heterogeneous and multiphase chemistry in the troposphere. *Science* 276, 1058–1065.

trihydrate. A convenient starting point in the present discussion will thus be an examination of surface reactions themselves. An added degree of complexity arises when the particle is liquid, as is the case for droplets in the troposphere, and possibly for stratospheric sulfate aerosol, which may be in the form of supercooled liquid sulfuric acid.

Formal kinetic equations for reactions on the surface of atmospheric particles often start from the *Langmuir adsorption isotherm*, which is the simplest of equations that expresses the partitioning of gas between surface and gas phases. The isotherm makes several assumptions, including one that states that all surface sites are equivalent and that there are no interactions between molecules adsorbed on them. With these assumptions, it may be shown that the *surface coverage*, θ_X , is given by the equation

$$\theta_X = \frac{bp_X}{1 + bp_X} \quad [16]$$

where b is a constant equal to the ratio of rate coefficients for adsorption onto the surface and desorption from it. For the low partial pressures of adsorbates present as minor constituents in the atmosphere, θ_X is likely to be very nearly a linear function of p_X , although the full equation might be needed for very strongly adsorbed reactants or for high partial pressures in the atmosphere. An extended treatment for the situation where two different species, X and Y , are adsorbed is straightforward, with the surface coverages θ_X and θ_Y both entering into the equation.

The kinetics of reaction for a single reactant are then developed by including a loss (probably decomposition) of the adsorbed molecules. If the rate coefficient for this first-order loss process is k_L , the rate of chemical change is

$$\text{Rate} = k_L \theta_X \approx k_L b_X p_X, \quad [17]$$

the second (approximate) equality applying for low θ_X . The overall kinetics are first order in p_X (and thus $[X]$). Analogous equations can obviously be developed for the case of X and Y both adsorbed on a surface, and interacting there. If both species are weakly adsorbed (small surface coverage), the kinetics will be second order, with a rate proportional to $p_X p_Y$. If one (or both) of the reactants is adsorbed too strongly to use the low-pressure limiting equation, then the full form of the adsorption isotherm must be employed.

A key parameter in the discussion of surface processes is the *uptake coefficient*, γ , which is the ratio of molecules lost to

a surface to the number of gas–surface collisions that occur. If the rate of collision of a molecule X with an area A of the surface is ω , then the rate of loss of X per unit volume, $-d[X]/dt$, is equal to $\gamma \cdot \omega/V$, where V is the volume of the system. The kinetic theory of gases shows that

$$\omega = \frac{\bar{c}A[X]}{4} \quad [18]$$

so that

$$-\frac{d[X]}{dt} = \frac{\gamma \bar{c}A[X]}{4V} \quad [19]$$

Now the loss of X may also be described in terms of phenomenological rate equations of the type

$$-\frac{d[X]}{dt} = k_S \{S\} [X] \equiv k'_S [X] \quad [20]$$

where $\{S\}$ represents the number of active surface sites per unit area and k_S and k'_S are second-order and the corresponding pseudo-first order rate coefficients for the surface loss process. It follows, from a comparison of eqns [19] and [20], that

$$k'_S = \frac{\gamma \bar{c}(A/V)}{4} \quad [21]$$

Uptake coefficients may be determined by a variety of experimental methods. Regardless of whether the molecule is removed by reaction on or within the particle, or by dissolving in it, eqn [21] provides the link between the kinetics of the uptake process and the uptake coefficient. It will be evident that the reactive uptake coefficient is equivalent to the *reaction probability*.

A complication obviously arises if a molecule does not react irreversibly, but can desorb again from a surface, or come out of solution to reenter the gas phase. In such cases, γ can apparently be time dependent, and the measurement of the variation of γ with time provides one way of examining these reversible processes. In the case of the atmosphere, the most important aspect concerns the partitioning of molecules between gaseous and liquid phases. Solubilities of gases at low solute concentrations obey *Henry's law*

$$[X(s)] = H_X p_X \quad [22]$$

where $[X(s)]$ is the concentration of X in solution, p_X is its pressure in the gas phase, and H_X is the Henry's law coefficient

(which is a function of temperature). Henry's law expresses an equilibrium situation, in which the fluxes of molecules into and out of the liquid are equal. However, it is straightforward to calculate the forward and reverse fluxes, and thus the net flux into the liquid, under nonequilibrium conditions. The first term comes immediately from eqn [20], while the second requires use of the diffusion equation for transport of the molecules from the bulk liquid to the interface. If the coefficient of diffusion for this latter process is D , then it may be shown that

$$\frac{1}{\gamma_t} = \frac{1}{\gamma_0} + \frac{\pi^{1/2} \bar{c}}{4H_X R T D^{1/2}} t^{1/2} \quad [23]$$

where γ_0 and γ_t are the uptake coefficients at time 0 and time t , respectively. The equation shows how H_X can be calculated from measurements of uptake coefficient as a function of time, or, conversely, how the variation of uptake coefficient with time may be estimated from a knowledge of the solubility of the gas. Note that at 'infinite' time, γ_t becomes zero: the system has reached equilibrium.

The material developed so far is applicable to both physical processes – adsorption, absorption, or solution – and chemical change. In the particular case of chemical change, we can envisage two possibilities. Either the reaction may involve an interaction of the gas-phase reactant with the surface or the bulk constituent of the particle, or it may involve reaction with some second species already adsorbed on, or dissolved in, the particle. The concepts set out earlier remain applicable in the second, 'bimolecular,' situation, but the value of $\{S\}$ at the surface (eqn [20]), or the concentration of the partner reactant Y, in solution, will be determined by factors similar to those already determining the adsorption or solubility of Y.

Finally, it is necessary to examine the kinetics of reaction *within* the liquid phase itself. The solvent obviously has the potential to exert a considerable influence on the course of chemistry in the liquid phase. In air at 1 atm pressure, and at ambient temperature, the molecules themselves occupy only roughly 0.2% of the total volume; in liquids, the molecules can make up half the volume. At pressures of 1 atm and below, we have been able to assume that the reactant molecules undergo essentially unhindered motion, and that assumption lies behind the various formulations of kinetics that we have discussed in previous sections. In distinction, in liquids the reactive molecules must squeeze past the solvent molecules (or each other, if one species is also the bulk liquid) if they are to reach each other and undergo reaction. Reactants, activated complexes or intermediates, and products can also all interact with the solvent. One manifestation of the interaction with intermediates is that energy removal in association reactions, such as the combination processes [XVI] or [XVII], is virtually instantaneous, and the systems always display pure second-order kinetics in the liquid phase, in contrast to the behaviour described in the last section for gas-phase reactants. Interactions of the reactants and the solvent (especially water) may make the formation of ions energetically more favourable than in the gas phase. New reaction channels may thus become accessible, and the kinetics of the processes can be influenced by the attractive or repulsive electrostatic interactions between the reactants, among many other factors.

Simple treatments of liquid-phase kinetics often start from the concept of the *encounter pair* of reactants that find themselves together within a *solvent cage*. Two extreme cases can be envisaged. In the first, the two species are very highly reactive towards each other, and undergo chemical transformation within a very few 'collisions' within the cage. The rate-determining process is then the diffusion of the reactants through the solvent to form the encounter pair, and the process is a *diffusion-controlled reaction*. At the other extreme, the activation energy for reaction may require the partners to pick up appreciable amounts of energy as they shake against each other within the cage, so that the kinetics are controlled by the rate of reaction within the cage, rather than by the rate at which they reach it. *Activation-controlled* reaction kinetics then result.

For many of the liquid-phase reactions of interest in atmospheric chemistry, the intrinsic reactivity of the partners is, indeed, very high, leading to diffusion-controlled kinetic behaviour. A very elementary treatment of the diffusion-controlled rate constant, k_d , leads to the equation

$$k_d = 4\pi r_{AB} D_{AB}, \quad [24]$$

where r_{AB} is a hypothetical *encounter distance* at which two partners A and B will react, and D_{AB} is the *diffusion coefficient* for the reactants.

The encounter distance *may* be roughly the sum of the gas-kinetic radii of the partners for neutral reactants, while the appropriate diffusion coefficient *may* be similar to a mean bulk diffusion coefficient of the reactants in the solvent. Making the assumptions that these values can be taken, and with typical values of $r_{AB} = 0.5$ nm and $D_{AB} = 1.3 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ (for Na^+ in H_2O), k_d is calculated as approximately $8 \times 10^{-18} \text{ m}^3 \text{ molecule}^{-1} \text{ s}^{-1}$ or, in the units that we have been using for rate coefficients so far, $8 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$. In liquid-phase kinetics, it is more conventional to use molar units for concentrations, so that the equivalent figure is $(6 \times 10^{23} \times 10^3 \times 8 \times 10^{-18}) \approx 5 \times 10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$. In whatever units this rate coefficient is expressed, it is evidently about 40 times smaller than the maximum gas-kinetic rate coefficient. In general, a rate coefficient of $>10^9 \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ for an aqueous-phase reaction is taken to be indicative of a diffusion-controlled mechanism.

One of the largest known rate coefficients for a condensed-phase process is that for the very important reaction

($1.4 \times 10^{10} \text{ dm}^3 \text{ mol}^{-1} \text{ s}^{-1}$ at 298 K). The magnitude mainly reflects the large diffusion coefficients in water of OH^- and, especially, of H^+ ; the rapid diffusion is itself a consequence of the special mechanisms by which these ions migrate in liquid H_2O .

Although the diffusion coefficient is most important in making reaction [XVIII] so fast, there is another factor operating that may be dominant in other reactions. The positive and negative ions attract each other, so that the effective encounter distance can be much greater than the gas-kinetic collision distance; that is, r_{AB} has to be replaced by r_{eff} in eqn [24]. For $r_{AB} = 0.5$ nm, straightforward electrostatic calculations indicate that r_{eff} ought to be about 0.2 nm for oppositely charged ions

(and 0.7 nm for like charges) in water with a relative permittivity of 78. However, it seems that this bulk permittivity is inappropriate to the highly ordered solvent molecules in the immediate vicinity of the ions, and that more realistic values of r_{eff} ought to be 10 nm and 10^{-9} nm for unlike and like charges. These values mean, of course, that oppositely charged ions will react 20 times faster than their neutral analogues, under similar conditions, while similarly charged ions can be assumed not to react at all.

While this discussion has so far centred on the behaviour of the atmospherically dominant class of diffusion-controlled reactions, some processes of interest are activation controlled. One characteristic of such reactions is that the activation energy may be smaller than for the equivalent gas-phase reaction, because the reactant pair undergoes many individual 'collisions' at each encounter, whereas, in the gas phase, the collision and the encounter are the same thing. A particularly interesting property shown by activation-controlled ionic reactions is that of the *kinetic salt effect*. Rate coefficients are affected by the presence of other ionic species present in the solution that do not themselves participate in the reaction. Interactions between oppositely charged partners are slowed down by the presence of such salts. In the atmosphere such effects may be of significance, since water droplets may contain substantial amounts of sea-salt or other similar species.

Synopsis

In this article, we first summarize the production processes for ions, including solar photoionization, photoelectron-impact ionization, and, mostly for X-ray photons, secondary and further electron impact ionization. In the auroral regions, impact of keV electrons and heavier particles is important. In these regions, very energetic secondary and further electrons are produced, which can further ionize the neutral constituents. We summarize the processes that are important in forming ion-density profiles. Chapman layer theory, while interesting pedagogically and historically, does not truly describe any real ionospheric layer. The *D*, *E*, *F*₁, and *F*₂ layers of the ionosphere are differentiated mostly by the production mechanisms for ions in the regions. Ions in the *F*₁ and *F*₂ regions are produced by EUV photons at roughly the same altitudes, but the *F*₁ region comprises molecular ions and the *F*₂ region mostly comprises atomic ions, which are differentiated by their loss processes: dissociative recombination for molecular ions in the *F*₁ region, and ion–molecule reactions and transport by diffusion for the atomic ions in the *F*₂ region. The chemistry of the *E* and *F* regions is discussed, followed by the chemistry of the *D* region. In the *E* and *F*₁ regions, the terminal ions are those for which the parent neutrals have low ionization potentials. In the *D* region, positive cluster ions, which terminate in proton hydrates, are ultimately formed. The terminal cluster ions are those for which the proton affinities are large. In this region of the ionosphere, there are also metal ion layers that are formed from metal atoms, which have extremely low ionization potentials. Metal atoms are formed in narrow layers by ablation of meteors, and are ionized by photoionization and charge transfer from the molecular ions O₂⁺ and NO⁺. In the lower *D* region, negative ions are formed, and they too may cluster. The terminal ions in this region are those for which the parent neutral has a large electron affinity. Mutual neutralization may be an important loss process in this region.

Introduction

Most of the ionosphere is to be found in the outer reaches of the atmosphere, the thermosphere, where the neutral temperature *T* increases with altitude from a minimum of 160–190 K near the mesopause, which is at about 85 km in the terrestrial atmosphere. At great heights, when the conductivity becomes large, the temperature eventually reaches a constant value, the exospheric temperature (*T*_∞). The value of the exospheric temperature depends on solar activity and ranges from about 700 to 2000 K in the terrestrial thermosphere. Most of the ionosphere consists of equal densities of positive ions and electrons, although in the lowest regions of the ionosphere, below ~75 km, significant densities of negative ions are present. The densities of positive atomic ions attain maximum values at the *F*₂ peak, near 300 km. Positive ions are initially produced by direct ionization of neutrals, the ultimate source of which is largely solar energy. This solar input can take the form of photons and photoelectrons during the daytime, or, in the auroral regions, of particles that have their origin in the magnetosphere: energetic electrons, and less frequently protons or even heavier particles. Some ions are created in the middle and lower atmosphere by cosmic ray bombardment.

The ions that are produced are then transformed by ion–molecule reactions, lost by recombination, or transported to other regions of the atmosphere. In the photochemical equilibrium (PCE) region, the densities of ions are not affected by transport. The upper boundary of the PCE region is the altitude where the time constant for loss of an ion by chemical reactions, *τ*_c is equal to that for transport by diffusion *τ*_D. The chemical time constant or lifetime is given by

$$\tau_c = \frac{n_i}{L_i} \quad [1]$$

where *n_i* is the number density of the ion and *L_i* is the total rate of loss by chemical reactions. *L_i* can be represented by

$$L_i = \sum_l k_l n_i n_l \quad [2]$$

In this equation *k_l* is the rate coefficient for reaction *l*, and *n_l* is the number density of the species that reacts with ion *i*. The time constant for transport by diffusion, *τ*_D, can be estimated as *H_i²/D_i*, where *D_i* is the diffusion coefficient of the ion and *H_i* = *kT_p/m_ig* is the scale height of the ion. In this formula, *k* is Boltzmann constant, *m_i* is the mass of the ion, and *g* is the acceleration of gravity; the plasma temperature *T_p* is given by the sum *T_e* + *T_i*, where *T_i* is the ion temperature and *T_e* is the electron temperature. In general the PCE boundaries vary widely from one ion to another and depend on the available loss processes. Above the PCE region, transport becomes important, and must be accounted for in determining the density profiles of the ions. At very high altitudes, chemistry is not significant, and the ion-density profiles are determined only by transport processes such as diffusion and convection.

The evolution and distribution of the number density of an ion *i* is determined by the continuity equation:

$$\frac{\partial n_i}{\partial t} + \nabla \cdot \Phi_i = P_i - L_i \quad [3]$$

In this equation the production rate *P_i* includes both direct production and production by chemical reactions and *Φ_i* is the flux of species *i*. At steady state, the change in number density with time, represented by the term *∂n_i/∂t*, is zero. If only the vertical direction is considered, the divergence of the flux becomes *∂φ_i/∂z*, where *φ_i* = *n_iw_i* and *w_i* is the vertical component of the velocity. Determining the velocity of an ion is fairly complex, since the motion of an ion is determined by collisions with neutrals and with other ions, which may

themselves be in motion. In addition, the ions and electrons are constrained to move together due to the polarization or charge separation electric field that arises when the electrons, which have larger mobilities and smaller masses, separate from the ions. The presence of external electric and/or magnetic fields further complicates the equations. In general, it is not possible to solve for the ion velocities in closed form. We can, however, write an approximate one-dimensional equation for the vertical velocity of a major ion i diffusing through a stationary neutral background gas

$$w_i = -D_a \sin^2 I \left[\frac{1}{n_i} \frac{\partial n_i}{\partial z} + \frac{m_i g}{k(T_e + T_i)} + \frac{1}{T_e + T_i} \frac{\partial(T_e + T_i)}{\partial z} \right] \quad [4]$$

where I is the magnetic dip angle and the ambipolar diffusion coefficient is $D_a = (1 + T_e/T_i)D_{in}$, where D_{in} is the ion-neutral diffusion coefficient. For a minor ion diffusing through a stationary major ion the velocity is given approximately by

$$w_j = -D_i \left[\frac{1}{n_i} \frac{\partial n_i}{\partial s} + \frac{T_e}{T_i} \frac{1}{n_e} \frac{\partial n_e}{\partial s} + \frac{m_i g}{kT_i} + \frac{1}{T_i} \frac{\partial(T_e + T_i)}{\partial s} \right] \quad [5]$$

where the path s is either along the magnetic field lines or along the vertical in the absence of a magnetic field. The ion diffusion coefficient D_i must account for collisions between the ion and the major ion j , as well as ion-neutral collisions. Equations for the ion velocities in more complicated (and more realistic) situations can be found in, for example, Schunk and Nagy (2009) or Banks and Kockarts (1977).

Ionization Processes

At low and midlatitudes, ionization may be produced by the interaction of solar extreme ultraviolet (EUV) photons, X-ray photons, photoelectrons, and secondary electrons with atmospheric gases. In the auroral regions, energetic electrons, protons, and occasionally heavier positively charged particles such as O^+ , precipitate into the atmosphere along the magnetic field lines

and ionize, excite, and dissociate atmospheric neutral species. Photons in the visible region of the solar spectrum, which are not absorbed appreciably by the atmosphere, arise from the photosphere of the sun. The visible portion of the solar spectrum can be approximated as that of a blackbody with a characteristic temperature of ~ 6000 K. The shorter wavelength ionizing photons, however, arise from parts of the solar chromosphere, the transition region to the corona, and the corona, where the temperatures range from 10^4 to 10^6 K. The solar EUV and X-ray spectra differ substantially from that of a blackbody, and vary markedly from low to high solar activity. An example of the solar photon flux for the wavelength range 0–2000 Å appropriate to low solar activity is shown in Figure 1.

The photon flux of solar radiation, $F_\lambda(z)$, in a small wavelength interval around λ at an altitude z , can, for the most part, be computed from the Beer–Lambert absorption law:

$$F_\lambda(z) = F_\lambda^\infty \exp(-\tau(\lambda, z)), \quad [6]$$

where F_λ^∞ is the solar photon flux outside the atmosphere and $\tau(\lambda, z)$ is the optical depth which, in the plane parallel approximation, is given by

$$\tau(\lambda, z) = \sum_j \int_z^\infty n_j(z') \sigma_j^a(\lambda) \sec \chi \, dz'. \quad [7]$$

Here, $n_j(z')$ is the number density of species j at altitude z' , $\sigma_j^a(\lambda)$ is the absorption cross section of species j at wavelength λ , and χ is the solar zenith angle, the angle of the line of sight to the sun with respect to the local vertical.

For χ greater than about 75° the optical depth must be computed by numerical integration over the path of the radiation in spherical geometry. For $\chi \leq 90^\circ$, the optical depth is

$$\tau(\lambda, z) = \sum_j \int_z^\infty n_j(z') \sigma_j^a(\lambda) \left[1 - \left(\frac{r_o + z}{r_o + z'} \right)^2 \sin^2 \chi \right]^{-0.5} dz'. \quad [8]$$

Figure 1 Solar photon flux as a function of wavelength from 18 to 2000 Å. From the SC#21REFW spectrum of Hinteregger (private communication).

For χ larger than 90° the optical depth is given by

$$\tau(\lambda, z) = \sum_j \left\{ 2 \int_{z_s}^{\infty} n_j(z') \sigma_j^a(\lambda) \left[1 - \left(\frac{r_o + z_s}{r_o + z'} \right)^2 \right]^{-0.5} dz' - \int_z^{\infty} n_j(z') \sigma_j^a(\lambda) \left[1 - \left(\frac{r_o + z}{r_o + z'} \right)^2 \sin^2 \chi \right]^{-0.5} dz' \right\} \quad [9]$$

where z_s is the tangent altitude, that for which the solar zenith angle is 90° along the line connecting the sun with the point of interest.

In a one-species atmosphere, the rate of absorption of solar photons of wavelength λ at altitude z is

$$q^a(\lambda, z) = F_\lambda(z) \sigma^a(\lambda) n(z). \quad [10]$$

It can be easily shown that, for a given wavelength, the absorption rate maximizes where the optical depth is unity. The altitudes of unit optical depth for photons characterized by wavelengths from the X-ray region to the far-UV at moderate resolution for overhead sun in the terrestrial atmosphere are shown in Figure 2. The shape of the curve reflects closely that of the absorption cross sections $\sigma^a(\lambda)$ of the major atmospheric gases. The absorption threshold of N_2 is about 12.14 eV; therefore, it does not absorb photons longward of about 1021 Å; the absorption threshold of O is 13.618 eV, and it does not absorb photons longward of about 910 Å. Thus in the terrestrial thermosphere and mesosphere, O_2 is the primary absorber between about 1000 and 2200 Å. At longer wavelengths, ~ 2200 –3000 Å, the near ultraviolet photons are absorbed by ozone in the middle atmosphere. Photons in the EUV (100–1000 Å) and parts of the far-UV (1000–1750 Å) are absorbed in the thermosphere and upper mesosphere, and X-rays ($\lambda < 100$ Å) are absorbed in the lower thermosphere and mesosphere. The strong solar Lyman alpha emission line at 1216 Å penetrates through a window in the O_2 absorption cross sections to an altitude of ~ 75 –80 km.

Photoionization of an atom or molecule (X) may be represented as

where e^* is a photoelectron. Photoelectrons produced by EUV photons are released with a range of energies that average less than 20 eV. The primary photoelectron spectrum near 170 km in the terrestrial atmosphere is shown in Figure 3, where it is compared to that at 100 km. The threshold energy at which an atom or molecule can be ionized is called the ionization potential (I_p). Ionization potentials of species commonly found in the ionospheres of the Earth, planets, and satellites are shown in Table 1. For molecules XY, photodissociative ionization may also occur:

In the latter equation, X and Y may be atomic or molecular fragments. The energy of the photoelectron in reaction [11] is given by

$$E_{pe} = h\nu - I_X - E_{ex} \quad [13]$$

and that in reaction [12] is

$$E_{pe} = h\nu - E_d - I_X - E_{ex}, \quad [14]$$

where I_X is the ionization potential of species X, E_d is the dissociation energy of molecule XY, and E_{ex} is the excitation energy of the product species. In photodissociative ionization, E_{ex} also includes the kinetic energy of the fragments, which has been found to be large for many atmospheric molecules.

The rate of ionization of a species j by photons of wavelength λ at an altitude z is given by

$$q_j^i(\lambda, z) = F_\lambda(z) \sigma_j^i(\lambda) n_j(z), \quad [15]$$

where $\sigma_j^i(\lambda)$ is the photoionization cross section. The expression above must be integrated over the solar ionizing spectrum to give the total photoionization rate, and all species must be included in the calculation of the optical depth to obtain the solar photon flux at a given wavelength. In addition, it is often necessary to take into account ionization to different final internal states of the products, so the partial cross sections or branching ratios to the different states are needed. In the atmospheres of magnetic planets, photoelectrons originating on the dayside may travel along the magnetic field lines to the

Figure 2 Altitude of unit optical depth in the terrestrial ionosphere as a function of wavelength in the extreme and far-UV wavelength regions.

Figure 3 Primary photoelectron flux in the terrestrial atmosphere at 170 km, near the F_1 peak, and at 100 km. Note that the spectrum at 100 km is significantly harder than that at 170 km.

Table 1 Ionization potentials (I_p) of common species in the atmospheres of the Earth and planets^a

High I_p (eV)		Medium I_p (eV)		Ionized by Ly α (eV)	
Species	I_p	Species	I_p	Species	I_p
He	24.59	H ₂ O	12.61	C ₄ H ₂	10.18
Ne	21.56	CH ₄	12.51	CH ₃	9.84

conjugate point on the nightside, where the field lines reenter the atmosphere. These suprathermal electrons may interact with the atmosphere producing ionization, excitation, and dissociation.

Auroral primary electrons have energies of the order of keV, and can ionize, excite, and dissociate atmospheric species. Some typical terrestrial auroral electron spectra are shown in Figure 4. Photoelectrons produced by photons with wavelengths

less than about 500 Å also have enough energy to carry out further ionization through electron-impact ionization:

and electron-impact dissociative ionization

In these reactions, e^* represents the energetic photoelectron or the auroral primary electron, e represents the energy degraded electron, and e' represents the secondary electron. The energy of the secondary electron $E_{e'}$ in an electron-impact ionization process [16] is given by

$$E_{e'} = E_{e^*} - I_X - E_{ex} - E_e, \quad [18]$$

where E_{e^*} is the energy of the initial primary or photoelectron, E_e is the energy of the degraded primary or photoelectron, and, as above, E_{ex} is the total excitation energy of the product ions and/or neutral fragments. For the dissociative ionization process [17], the dissociation energy of the XY molecule must also be subtracted as well. It should be noted that these ionization processes must compete with other processes that energetic electrons can carry out, such as inelastic rotational, vibrational, and electronic excitation, and (for molecules) dissociation; at low energies elastic collisions with the ambient electrons must also be considered.

The ionization rate due to electron impact $q_j^{ei}(z)$ of a species j with ionization potential I_j is given by

$$q_j^{ei}(z) = n_j(z) \int_{I_j}^{\infty} \int_0^{(E-I_j)/2} \frac{d\sigma_j^{ei}(E)}{dW_s} \frac{dF(z, E)}{dE} dW_s dE, \quad [19]$$

where $dF(z, E)/dE$ is the differential flux of primary electrons with respect to energy, and $d\sigma_j^{ei}(E)/dW_s$ is the differential cross section for production of a secondary electron with energy W_s by a primary electron with energy E . The integral over secondary energies W_s terminates at $(E - I_j)/2$ because the

Figure 4 Typical auroral spectra derived from a coupled experiment of ultraviolet images from the POLAR satellite and electron densities derived from the Sondrestrom incoherent scatter radar in 1996. E_0 is the characteristic energy and F_E is the energy flux of the spectrum. Taken from Doe, R.A., Kelly, J.D., Lummerzheim, D., Parks, G.D., Brittnacher, M.J., Germany, G.A., Span, J., 1997. Initial comparison of POLAR UVI and Sondrestrom IS radar estimates for auroral electron energy flux. *Geophysical Research Letters* 24, 999–1002.

secondary electron is by convention considered to be the one with the smaller energy. Since the average energy of photoelectrons produced by EUV photons is less than 20 eV, the error incurred in cutting off the integral in eqn [19] at 300 eV or so, rather than $(E - I_j)/2$ is not serious, although for high energy auroral electrons and for photoelectrons produced by solar X-ray ionization, a larger upper limit must be used.

The differential cross section for the production of a secondary electron with energy W_s is usually adopted from an empirical formula that is normalized so that

$$\sigma_j^{ei}(E) = \int_0^{(E-I_j)/2} \frac{d\sigma_j^{ei}(E)}{dW_s} dW_s, \quad [20]$$

where $\sigma_j^{ei}(E)$ is the measured total ionization cross section at primary electron energy E . One formula in common use is:

$$\frac{d\sigma_j^{ei}(E)}{dW_s} = \frac{A(E)}{1 + (W_s/\bar{W})^{2.1}}, \quad [21]$$

where $A(E)$ is a normalization factor and $\bar{W}$ is an empirically determined constant, which has been found to be equal to within about 50% of the ionization potential for a number of species.

In practice, discrete energy loss of electrons can be easily treated numerically if the electrons can be considered to lose their energy locally, which is generally a good approximation for photoelectrons near and below the peak altitude for production of ions. Since elastic scattering of electrons by neutrals mostly changes the direction of the incident electron, and not its energy, only inelastic processes such as excitation, dissociation, and ionization need to be considered in this approximation. For ionization, of course, the energy distribution of the secondary

electrons must be taken into account, but not the scattering angles of either the primary or secondary electron. Below the lowest thresholds for excitations, energetic electrons lose their energy in elastic collisions with thermal electrons. This process and rotational excitation are often approximated as continuous rather than as discrete excitations.

The slowing down of high-energy auroral primary electrons or energetic photoelectrons arises from both elastic and inelastic scattering processes, and cannot be treated using the local energy loss approximation. In solving the equations for electron transport, the angle through which the primary electron is scattered, as well as the change in energy of the primary electron and the production of any secondaries must be taken into account. Electron-transport methods should also be applied to determine the spectrum of high-altitude photoelectrons, which stream up from near the ionospheric peak. Discussion of the electron-transport equations can be found, for example, in the monographs by Rees (1989) and by Schunk and Nagy (2009).

Several methods for approximating the energy deposition of auroral electrons are currently in use. In the continuous slowing down approximation (CSDA), the electrons are assumed to lose their energy continuously and at the same rate, and to be scattered only in the forward direction. The CSDA provides only a rough approximation to the depth of penetration of the electrons, and to the rates of ion production and other energy loss processes. In the 'two-stream' approximation, the electrons are assumed to be scattered in either the forward or backward direction. Implementation of this method requires only the backscattering probabilities, rather than complete angular differential cross sections. The method has been generalized to multistream models, in which the solid angle range of the electrons is divided into 20 or more intervals, so more or less complete differential cross sections are required. Monte Carlo

methods have also been used to model auroral precipitation and photoelectron energy deposition.

Ion Density Profiles

Density profiles of molecular ions are often approximated as idealized Chapman layers. A Chapman layer is one in which a single ion is produced from a single neutral species in an isothermal atmosphere by interactions with photons of a single wavelength. The positive ions are assumed to be destroyed by recombination with electrons or negative ions. Dissociative recombination (DR) is the process of electron recombination with a molecular ion that leads to the production of neutral fragments:

PCE is assumed to prevail in a Chapman profile.

The photoionization rate q^i in a Chapman layer is given by eqn [15], with the subscripts for various species and wavelengths removed:

$$q^i(z) = F(z)\sigma^i n(z). \quad [23]$$

Here, n is the number density of the single ionizable species, $F = F^\infty \exp(-\tau)$ is the local solar photon flux, and σ^i is the ionization cross section at the single wavelength λ . The acceleration of gravity g is also assumed to be constant, and therefore the density profile of the neutral species in a Chapman layer is given by $n(z) = n_0 \exp(-z/H)$, and the optical depth τ is $nH\sigma^a \sec \chi$, where the constant scale height H of the neutral species is given by kT/mg . In this expression, T is the (assumed) constant thermospheric temperature, and m is the mass of both the single neutral species and the single ion. The ionization cross section is sometimes expressed as

$$\sigma^i = \eta^i \sigma^a, \quad [24]$$

where η^i is the ionization efficiency.

The maximum photoionization rate occurs where the optical depth τ is unity, and therefore where $n_{\max} = 1/(\sigma^a H \sec \chi)$. The maximum photoionization rate is

$$q_{\max, \chi}^i = \frac{F^\infty}{e} \frac{\sigma^i}{\sigma^a H \sec \chi} = \frac{q_{\max, 0}^i}{\sec \chi}, \quad [25]$$

where $q_{\max, 0}^i$ is the maximum ionization rate for $\chi = 0$. Thus the maximum ionization rate decreases with increasing solar zenith angle. We can obtain a simple expression for the ionization rate by defining the altitude of maximum ionization for overhead sun as $z = 0$. Then $n_0 = (\sigma^a H)^{-1}$, and, expressing F^∞ in terms of $q_{\max, 0}^i$, the photoionization rate is

$$q^i(z) = q_{\max, 0}^i \exp\left[1 - \frac{z}{H} - \sec \chi \exp(-z/H)\right]. \quad [26]$$

The third term in the exponent of eqn [26] is significant only near and below the peak. At high altitudes ($z \rightarrow \infty$) the ionization rate decreases exponentially, following that of the neutral species from which it is produced, and below the peak (as $z \rightarrow -\infty$), the ionization rate rapidly approaches zero. As the solar zenith angle increases, the altitude of the production peak rises and the magnitude of the production rate maximum decreases. Figure 5 shows a production profile for an idealized Chapman layer on a semilog plot, which clearly shows the asymmetry with respect to the maximum.

Figure 5 Ideal Chapman absorption (or production) rate profile for solar zenith angles of 0, 30, 60, and 75°. The altitude is scaled so that $z = 0$ is the altitude of maximum absorption for overhead sun.

In a Chapman layer, PCE prevails, and therefore the photoproduction rate of the molecular ion is equal to the loss rate due to DR (process [22]):

$$q^i(z) = \alpha_{\text{DR}} n_i(z) n_e(z) = \alpha_{\text{DR}} n(z)^2 \quad [27]$$

where α_{DR} is the DR coefficient and n_e is the electron density. Therefore, the density of the ion as a function of altitude is given by

$$n(z) = \left(\frac{q^i(z)}{\alpha_{\text{DR}}}\right)^{1/2} = \left(\frac{q_{\max, 0}^i}{\alpha_{\text{DR}}}\right)^{1/2} \exp[1/2 - z/(2H) - 1/2 \sec \chi \exp(-z/H)]. \quad [28]$$

At altitudes above the peak, the scale height of the ion in a Chapman layer approaches $2H$.

Actual ion-density profiles differ from the ideal Chapman profile for several reasons. First, in a real atmosphere, ionization is produced by solar photons over a wide range of wavelengths, from the EUV to the X-ray regions; these photons reach unit optical depth over a wide range of altitudes, as Figure 2 shows. Second, although thermospheric neutral temperatures reach constant values of T^∞ at high altitudes, they are usually characterized by increasing temperatures near the altitude of peak ion production. More important, T_e and T_i are not equal to the neutral temperature T_n , but diverge substantially from T_n near or slightly above the ion peak. The DR coefficient α_{DR} is not constant, but varies with the particular ion and inversely with T_e . The major ion produced is often transformed by ion-molecule reactions before it can undergo DR. Most important, photoionization is supplemented by electron-impact ionization, the peak ionization rate of which occurs slightly below the peak photoionization rate of EUV photons, and greatly below the peaks in the photoionization rate due to the absorption of X-rays. In fact, energetic photoelectron and secondary electron impact are the major sources of ionization in the regions in

which X-rays are absorbed. Energetic electrons are not extinguished, as are photons, in producing an ion. Although precipitation of auroral electrons may be characterized by a production profile that appears similar to that of a Chapman-type layer, the actual ion production and density profiles differ greatly from the idealized profile because of the latter effect and the fact that auroral electron spectra are far from monoenergetic (Figure 4).

All these factors combine to make the shape of real ion-density peaks very much broader than that of an ideal Chapman layer. Chapman theory predicts that peak magnitudes vary as $(\cos \chi)^{1/2}$, and as $F^{1/2}$ but underlying this prediction is the assumption that the neutral atmosphere does not change with either χ or F , which is clearly insupportable. Also, photon fluxes in various regions of the ionizing spectrum vary differently with solar activity. Nonetheless, the idealized concept of the Chapman layer, while not strictly applicable to real ionospheres, is useful for a pedagogical first order understanding of the ion production and density peak shapes, and their behavior as the solar zenith angle and solar fluxes change.

Ionospheric Regions

The division of the ionospheres of the Earth and planets into regions is based on the structure of the terrestrial ionosphere, which consists of overlapping layers of ions. These layers are the result of changes in both the composition of the thermosphere and the sources of the ionization, and are illustrated in Figure 6. The major molecular ion layer is the F_1 layer, which is produced by absorption of EUV photons with wavelengths between about 200 and 1000 Å by the major thermospheric species. The F_1 peak appears where the ion production due to solar EUV absorption as a whole maximizes. The column densities of the neutral absorbing species in the F_1 region are of the order of 10^{17} cm^{-2} . The ions in the F_1 region are mostly molecular and the ions are in PCE. In the terrestrial atmosphere, the F_1 peak appears in the electron density profile only as a ledge in the range 170–200 km. In the ionospheres of Venus and Mars, the F_1 peaks are the absolute maxima of the electron density profiles.

The F_2 region, if it appears, is the highest region in an ionosphere, where the major ions are monatomic. The F_2 region is still considered to be part of the F region because the production rate profile of the atomic ions peak in the same altitude range as those of the F_1 peak. The peak density occurs higher than that of the F_1 peak, however, because atomic ions are not destroyed by DR; even at fairly high altitudes, the major chemical loss processes are reactions with the thermospheric neutrals. The F_2 peak occurs at approximately where the chemical lifetime of the atomic ion is equal to the characteristic time for transport by diffusion, and PCE does not apply to this region.

The E region is below the F_1 region. Here the ions are produced by shorter and longer wavelength solar photons than those that produce the ions in the F_1 region. These photons include soft X-rays ($\lambda = 10\text{--}100 \text{ Å}$), which are characterized by smaller cross sections than are those of the EUV, and which therefore penetrate further into the atmosphere. In the terrestrial ionosphere, E -region ions may also be produced by absorption of solar Lyman β at 1026 Å, which can ionize O_2 and NO .

Figure 6 Schematic diagram of the various regions in the terrestrial ionosphere, and the major sources of ion production. From Bauer, S.J., Lammer, H., 2004. Planetary Aeronomy. Springer, Berlin.

High-energy photons in the soft X-ray region of the spectrum produce high-energy photoelectrons, which are capable of further ionization. The secondary electrons produced may themselves produce further ionization. In fact, as noted above, ion production in the E region is dominated by electron impact, rather than by photoionization. A comparison of the primary photoelectron fluxes near the F_1 peak of the Earth with those in the E region near 100 km has been presented in Figure 3. The spectrum near 100 km is considerably harder than that at the F_1 peak near 170 km. The E region is often considered to be a Chapman layer, although the physics and chemistry of this region diverge significantly from those of such an idealized concept. Because photons with wavelengths below 100 Å exhibit larger solar activity variations than those with longer wavelengths in the EUV region, the peaks of the ionospheric E regions tend to exhibit larger solar activity variations than do the F_1 peaks, and are more sensitive to the presence of solar flares.

In the D region, the ion production is dominated by harder solar X-rays, with wavelengths less than 10 Å, and for Earth, by ionization of NO by Lyman alpha photons, which penetrate to low altitudes through an accidental window in the O_2 absorption cross sections. This phenomenon is unique to the terrestrial thermosphere where the EUV absorption is dominated by O_2 . In CO_2 -dominated atmospheres, Lyman alpha does not penetrate to such low altitudes. The ions produced in this region are in PCE, but, as we will show below, the production mechanisms and the chemistry of the ions preclude the description of this region as a Chapman layer.

Chemistry of the *E* and *F* Regions

The major ions produced in the ionospheres of the Earth and planets are usually those from the major neutral thermospheric species. On Earth, the major ions produced by solar photons and photoelectrons are N_2^+ , O_2^+ , and O^+ . In the presence of sufficient neutral densities, however, the ions are transformed by ion–molecule reactions. In the *E* and *F* region, ion–molecule reactions may be either charge-transfer reactions, such as

in which only an electron is transferred between the two species, or ion–atom interchange reactions, such as

which involve rearrangement of the molecular bonds.

Reactions between neutrals and ions are generally faster than neutral–neutral reactions because of the longer range forces involved. The attraction between a charged particle and a nonpolar neutral is produced by the induction or polarization force: that between an ion and the dipole moment that is induced in the neutral by the proximity of the ion. The magnitude of this force depends on the polarizability α of the neutral and the charge q on the ion. The long-range potential between an ion of mass m_i and a neutral with mass m_n at separation r is $-\alpha q^2/2r^4$, and the collision or Langevin rate coefficient for energies less than a few eV is given by

$$k_L = 2\pi q(\alpha/\mu)^{1/2}, \quad [31]$$

where

$$\mu = \frac{m_n m_i}{m_n + m_i} \quad [32]$$

is the reduced mass of the reactants. The Langevin rate coefficient is temperature independent, because the capture cross section is inversely proportional to the velocity. In traditional units, for a singly charged ion, the Langevin rate coefficient can be simply calculated as

$$k_L = 2.34 \times 10^{-9} (\alpha/\mu)^{1/2} \text{ cm}^3 \text{ s}^{-1} \quad [33]$$

where μ is in unified mass units and the polarizability α is given in $\text{\AA}^3$ or 10^{-24} cm^3 . Polarizabilities of common atmospheric species are presented in Table 2. If the neutral has a permanent dipole or quadrupole moment, then a term must be added that represents the force between the charged particle and the dipole or quadrupole to that for the ion-induced dipole (e.g., Su and Bowers, 1979).

In the presence of sufficient neutral densities, there is a tendency for ion–molecule reactions to transform ions whose parent neutrals have high ionization potentials into those whose parent neutrals have low ionization potentials. This is merely a convenient restatement of the requirement that reactions be exothermic, and is rigorously true only for charge-transfer reactions. In practice, however, it is true for most other ion–molecule reactions, such as ion–atom interchange, because dissociation energies of typical atmospheric molecules differ less than ionization potentials. Notable exceptions to this tendency are the reactions

and

Even though the ionization potential of C is 11.3 eV, and that of CO is 14.01 eV, the lower ionization potential is counteracted by the large dissociation energy of CO (11.1 eV), which is twice that of CO₂ (5.45 eV). In reaction [35], the difference between the ionization potentials of N₂ (15.58 eV) and N (14.54 eV) is counteracted by the large dissociation energy of N₂ (9.76 eV) compared to that of NO (6.49 eV). Reaction [35] tends to proceed, however, via charge transfer, producing NO⁺, rather than by abstraction.

A schematic diagram of ion chemistry in the *F* and *E* regions of the ionospheres of the terrestrial planets is shown in Figure 7. In this diagram, the ionization potentials of the parent neutrals decrease downward. Where collisions are sufficiently frequent, near the *F*₁ peak and below, ionization tends to flow from the ions near the top of the diagram to those near the bottom. This principle is illustrated by the chemistry of N₂⁺. N₂ has a very high ionization potential, and N₂⁺ is produced in large quantities in the terrestrial ionosphere by photoionization and electron-impact ionization, but its steady-state densities are small. For N₂⁺, few chemical production mechanisms exist, but many loss processes are possible. Figure 8 shows altitude profiles of the production and loss mechanisms of N₂⁺ for a model of the terrestrial ionosphere.

By contrast, NO has the lowest ionization potential of the major *E*- and *F*-region ionospheric species. There are many mechanisms for the production of NO⁺, but only one significant loss process, DR:

Even in the absence of neutral NO, NO⁺ is produced by ion–atom interchange reactions in oxidizing atmospheres. The major sources of NO⁺ for a model of the terrestrial ionosphere are shown in Figure 9. The lower thermospheres of Venus and

Figure 7 Schematic diagram of the major chemical reactions in the terrestrial ionosphere. The ionization potentials of the parent neutrals, which are shown below each ion, decrease from top to bottom. Where collisions are sufficiently frequent, ionization tends to flow downward on the diagram. From Fox, J.L., 2011. Dissociative recombination data needs for the aeronomy community. In: Guberman, S.L., Orel, A.E. (Eds.), *Dissociative Recombination: Theory, Experiments, and Applications*. Journal of Physics: Conference Series 300, IOP Publishing, jpcs.iop.org, Bristol, 012025. <http://dx.doi.org/10.1088/1742-6596/300/1/012025>.

Mars are dominated by CO_2 , with a small admixture of about N_2 (2–4%); O_2 is only a minor species, comprising less than 1% of either thermosphere. Because of the small ionization potentials of NO and O_2 , however, NO^+ and O_2^+ are the major ions in the E and F_1 regions of Venus and Mars, as well as in those of the Earth. Measured rate coefficients for many ion-molecule reactions have been compiled, for example, by Anicich (1994, 2003) and by Ikezoe et al. (1987). About 200 rate coefficients for reactions in oxidizing thermospheres/ionospheres have been compiled by Fox and Sung (2001). Richards (2011) has discussed the most important ~ 40 ion-molecule and DR reactions in the terrestrial F region for four ions that are in PCE: N_2^+ , O_2^+ , NO^+ , and N^+ .

In the reducing atmospheres of the outer planets and satellites, where hydrogen is abundant, and at low enough altitudes where collisions with neutrals are sufficiently frequent, ionization flows from species formed by protonation of neutrals that have smaller proton affinities to those formed by protonation of neutrals that have large proton affinities. Proton affinities for several major and minor atmospheric species of atmospheric importance are shown in Table 3. There are no *in situ* measurements of the ion composition of the outer planets, but models predict that H_3^+ and hydrocarbon ions dominate F_1 and E regions of these ionospheres. The thermosphere of Titan is composed of N_2 , CH_4 , and

H_2 , and measurements made by the Cassini Ion and Neutral Mass Spectrometer show that the ionosphere is quite rich in hydrocarbon ions with masses up to about 100 Da (unified mass units), the instrumental limit. The ion mass spectra show that the densities of hydrocarbon ions are clustered around masses that are separated by 12–14 Da, and the most important ion in each cluster is that for which the proton affinity is largest. Proton affinities are also important for the H-containing ions in the E and F regions of the terrestrial planets, and to the chemistry of the terrestrial D region, which will be discussed below.

Molecular ions are efficiently destroyed by DR (process [22]) in regions where the electron densities are sufficiently large. The long-range Coulomb forces between the ion and electron lead to DR rate coefficients (α_{DR}) that are large, in the order of a few $\times 10^{-7} \text{ cm}^3 \text{ s}^{-1}$ at thermal values of T_e , and simple theory predicts a negative temperature dependence of the rate coefficient of $T_e^{-0.5}$. In practice, however, the values of α_{DR} of common atmospheric ions are found to vary as $T_e^{-(0.5 \pm 0.25)}$. Some DR coefficients relevant to the ionospheres of the terrestrial planets are given in Table 4. Florescu-Mitchell and Mitchell (2006) have reviewed computed and measured DR coefficients and branching ratios for various sets of products compiled from the literature prior to 2006.

Table 4 Selected dissociative recombination (DR) rate coefficients

Reaction	Rate coefficient, $\text{cm}^3 \text{s}^{-1}$
$\text{CO}_2^+ + e \rightarrow \text{CO} + \text{O}$	$4.2 \times 10^{-7} (300/T_e)^{0.75}$
$\text{CO}^+ + e \rightarrow \text{C} + \text{O}^a$	$1.75 \times 10^{-7} (300/T_e)^{0.55}$
$\text{CO}^+ + e \rightarrow \text{C} + \text{O}(^1\text{D})$	$0.33 \times 10^{-7} (300/T_e)^{0.55}$
$\text{CO}^+ + e \rightarrow \text{C}(^1\text{D}) + \text{O}$	$0.216 \times 10^{-7} (300/T_e)^{0.55}$
$\text{O}_2^+ + e \rightarrow \text{O}(^3\text{P}) + \text{O}(^3\text{P})^b$	$4.3 \times 10^{-8} (300/T_e)^{0.70}$ for $T_e \leq 1200 \text{ K}$ $1.63 \times 10^{-8} (1200/T_e)^{0.56}$ for $T_e \geq 1200 \text{ K}$
$\text{O}_2^+ + e \rightarrow \text{O}(^3\text{P}) + \text{O}(^1\text{D})$	$8.2 \times 10^{-8} (300/T_e)^{0.70}$ for $T_e \leq 1200 \text{ K}$ $3.1 \times 10^{-8} (1200/T_e)^{0.56}$ for $T_e \geq 1200 \text{ K}$
$\text{O}_2^+ + e \rightarrow \text{O}(^1\text{D}) + \text{O}(^1\text{D})$	$6.05 \times 10^{-8} (300/T_e)^{0.70}$ for $T_e \leq 1200 \text{ K}$ $2.29 \times 10^{-8} (1200/T_e)^{0.56}$ for $T_e \geq 1200 \text{ K}$
$\text{O}_2^+ + e \rightarrow \text{O}(^1\text{D}) + \text{O}(^1\text{S})$	$9.75 \times 10^{-9} (300/T_e)^{0.70}$ for $T_e \leq 1200 \text{ K}$ $3.69 \times 10^{-9} (1200/T_e)^{0.56}$ for $T_e \geq 1200 \text{ K}$
$\text{N}_2^+ + e \rightarrow \text{N} + \text{N}(^2\text{D})$	$1.01 \times 10^{-7} (300/T_e)^{0.39}$
$\text{N}_2^+ + e \rightarrow \text{N}(^2\text{D}) + \text{N}(^2\text{D})$	$1.01 \times 10^{-7} (300/T_e)^{0.39}$
$\text{N}_2^+ + e \rightarrow \text{N} + \text{N}(^2\text{P})$	$1.76 \times 10^{-8} (300/T_e)^{0.39}$
$\text{NO}^+ + e \rightarrow \text{N}(^2\text{D}) + \text{O}$	$3.40 \times 10^{-7} (300/T_e)^{0.5}$
$\text{NO}^+ + e \rightarrow \text{N} + \text{O}$	$0.60 \times 10^{-7} (300/T_e)^{0.5}$
$\text{H}_3\text{O}^+ + e \rightarrow \text{H}_2\text{O} + \text{H}$	$1.9 \times 10^{-7} (300/T_e)^{0.83}$ for $T_e \leq 1000 \text{ K}$ $7.0 \times 10^{-8} (1000/T_e)^{1.1}$ for $T_e \geq 1000 \text{ K}$
$\text{H}_3\text{O}^+ + e \rightarrow \text{OH} + \text{H}_2$	$1.06 \times 10^{-7} (300/T_e)^{0.83}$ for $T_e \leq 1000 \text{ K}$ $3.9 \times 10^{-8} (1000/T_e)^{1.1}$ for $T_e \geq 1000 \text{ K}$
$\text{H}_3\text{O}^+ + e \rightarrow \text{OH} + \text{H} + \text{H}$	$4.56 \times 10^{-7} (300/T_e)^{0.83}$ for $T_e \leq 1000 \text{ K}$ $1.68 \times 10^{-7} (1000/T_e)^{1.1}$ for $T_e \geq 1000 \text{ K}$
$\text{H}_3\text{O}^+(\text{H}_2\text{O})_n + e \rightarrow$ neutrals	$(0.5 + 2n) \times 10^{-6} (300/T_e)^{0.5}$
$\text{Na}^+(\text{CO}_2) + e \rightarrow$ $\text{N} + \text{CO}_2$	5×10^{-6} at 300 K

^aBranching ratios interpolated at 2500 K from the values measured at collision energies of 0.0, 0.4, 1.0, and 1.5 eV.

^bRecently it has been shown that the branching ratios for O_2^+ DR vary with collision energy (e.g., Peverall, R., Rosen, S., Peterson, J.R., et al., 2001. J. Chem. Phys. 114, 6679–6689) and with vibrational level of the O_2^+ ion (e.g., Petrigiani, A., van der Zande, W.J., Cosby, P.C., et al., 2005. Journal of Chemical Physics 122, 014302). Adapted from Fox, J.L., Sung, K.Y., 2001. Solar activity variations in the Venus ionosphere/thermosphere. J. Geophys. Res. 106, 21305–21335, with additional data from the compilation of Florescu-Mitchell, A.I., Mitchell, J.B.A., 2006. Dissociative recombination. Physics Report 430, 277–374.

Since atomic ions cannot undergo DR, the only recombination mechanism available to an ion such as O^+ is radiative recombination:

Radiative recombination is the reverse of photoionization, and the spectrum of photons emitted is a continuum with a cutoff at the ionization potential of the product neutral atom. Radiative recombination reactions are very slow, with rate coefficients of the order of $10^{-12} \text{ cm}^3 \text{s}^{-1}$ at 300 K. Because the electron and ion must remain in close proximity long enough for the emission of a photon, such reactions tend to have strong inverse temperature dependences.

Because radiative recombination is slow, it is rarely a major loss process for an atomic ion. In the presence of sufficient neutral densities, atomic ions are transformed into molecular ions via ion–molecule reactions. The molecular ions are then destroyed by DR. For example, O^+ is produced mainly by photoionization and electron-impact ionization of O ; the peak in the production rate of O^+ in the terrestrial ionosphere is near 175 km. In the *E* and *F* regions of the

ionosphere, chemical loss of O^+ is dominated by reaction with O_2

and with N_2

Altitude profiles of the most important sources and chemical sinks of O^+ are shown in Figure 10.

Since the densities of the major neutral species decrease exponentially with altitude, the rates of ion–molecule reactions also decrease with altitude. If these reactions were the only loss process for atomic ions, their densities would increase with altitude indefinitely. At altitudes above that at which the chemical lifetime of the ion, τ_c , is equal to its diffusion time, τ_{Di} , the major loss process for an atomic ion is diffusion. In the terrestrial ionosphere, this effect produces an F_2 peak near 300 km, where the O^+ maximum density of $\sim 10^6 \text{ cm}^{-3}$ is also the absolute maximum for the ionosphere, as shown in Figure 11, where we present ion-density profiles for the *E* and *F* regions of the terrestrial atmosphere from a model.

Figure 10 Major production and loss mechanisms for O^+ from a model of the terrestrial ionosphere. From Dalgarno, A., Fox, J.L., 1994. Ion chemistry in atmospheric and astrophysical plasmas. In: Ng, C.Y., Baer, T., Powis, I. (Eds.), Unimolecular and Bimolecular Ion-Molecule Reaction Dynamics. Wiley and Sons, New York, pp. 1–85.

Figure 11 Major ion density profiles for the E , F_1 , and F_2 regions of the terrestrial ionosphere. From Dalgarno, A., Fox, J.L., 1994. Ion chemistry in atmospheric and astrophysical plasmas. In: Ng, C.Y., Baer, T., Powis, I. (Eds.), *Unimolecular and Bimolecular Ion-Molecule Reaction Dynamics*. Wiley and Sons, New York, pp. 1–85.

Such pronounced F_2 peaks do not appear on Mars and Venus for a number of reasons, including smaller mixing ratios of O and O_2 , and smaller neutral scale heights. This combination leads to lower altitude and smaller density peaks in the O^+ profiles, which may not be visible in the electron density profiles. On the outer planets, however, H^+ is predicted to form a prominent F_2 peak, the magnitude and altitude of which is difficult to reconcile with the radio occultation electron density profiles returned from spacecraft.

D-Region Ion Chemistry

The D region of the terrestrial ionosphere is found in the altitude range of approximately 50–100 km. Photoionization of NO by solar Lyman alpha photons at 1216 Å, and ionization of all neutral species by hard X-rays are supplemented by absorption of cosmic rays, which deposit their energy over a large altitude range. These sources are, however, highly variable. The solar X-ray fluxes depend on the 11-year solar cycle and the presence or absence of flares on the solar disk. The cosmic ray flux is anticorrelated with solar activity. Photoionization of $O_2(a^1\Delta_g)$ has also been suggested as a source of ionization in the D region. $O_2(a^1\Delta_g)$ is a metastable electronically excited state of O_2 , which has an ionization potential of 11.1 eV, and a lifetime against radiation to the ground state of more than 4000 s. It is formed by photodissociation of ozone in the mesosphere. Among FUV photons capable of ionizing $O_2(a^1\Delta_g)$, only those in the limited range 1090–1116 Å and Lyman beta at 1026 Å penetrate below 90 km.

The ions in the D region can be considered to be in PCE. Just as in the E and F_1 regions of the ionosphere, regardless of the species ionized, chemical reactions in the D region tend to transform ions produced, such as N_2^+ for which the parent neutral has a high ionization potential, to the ions O_2^+ and

NO^+ , and to metal ions, for which the parent neutrals have very low ionization potentials. Neutral metal atoms, such as Fe, Mg, Na, and Ca, are produced in the mesosphere by ablation of meteoroids, which enter the atmosphere continuously. The neutral metal atoms form narrow layers at about 90 km that are a few kilometers thick. The metal atoms may react with O and O_3 to form oxides and other reservoir species, and they are ionized by photoionization as well as charge-transfer reactions. At low enough altitudes the metal ions form metal oxide ions or clusters with N_2 , CO_2 , or H_2O . These cluster ions may undergo DR, which releases the neutral metal atoms. The chemistries of each meteoric metal atom and ion, although similar, differ in details; the chemistry of this region of the atmosphere is quite complex. Plane (2002) has presented a detailed overview of the subject.

Figure 12 shows the density profiles of the most important classes of positive ions, including molecular, metal, and cluster ions, between ~80 and ~100 km, as measured by a rocket. At sufficiently low altitudes, where the background neutral densities are large, the terminal ions are not NO^+ or O_2^+ because they cluster efficiently with background molecules, such as N_2 or O_2 . Mass spectrometers carried aboard rockets have shown that below an altitude known as the ‘transformation altitude’, the diatomic positive ions O_2^+ and NO^+ are transformed to large polyatomic cluster ions. The transformation altitude is determined by the temperature, electron densities, and neutral densities. The large measured masses correspond mostly to proton hydrates $H^+(H_2O)_n$ (also expressed as $H_3O^+(H_2O)_{n-1}$) where n is 1, 2, 3, or 4, with $n = 2$, $n = 1$, and $n = 3$ dominating. H_3O^+ , the hydronium ion, has been shown to be a stable species in the gas phase.

The formation of cluster ions may begin with the three-body recombination of O_2^+ with O_2 ,

Figure 12 Altitude profiles of the major ion categories: molecular ions, cluster ions, and metal ions. Taken from Kopp, E., Balsiger, F., Murad, E., 1995. Silicon molecular ions in the *D*-region. *Geophysical Research Letters* 22, 3473–3476.

where *M* is an abundant background species. Unless the O_2^+ (O_2) species redissociates, reaction [40] may be followed by the two-body switching reaction to form a cluster with a water molecule, which has a dipole moment:

Since $O_2^+(H_2O)_n$ photodissociates or undergoes collisional dissociation for *n* larger than 1, further hydration of O_2^+ is unlikely. Direct transformation to a proton hydrate

or to a proton hydrate clustered with a hydroxyl radical, $H^+(H_2O)(OH)$, is more probable. The latter species may then undergo switching of the hydroxyl radical with H_2O , forming $H^+(H_2O)_2$. $H^+(H_2O)_2$ may also be formed by a termolecular hydration reaction

Similar three-body hydration reactions may then continue to occur, producing $H^+(H_2O)_3$, $H^+(H_2O)_4$, and even larger proton hydrates. The terminal cluster ions are determined partly by the proton affinities of the molecules to which they cluster (see Table 3).

The transformation of NO^+ to proton hydrates is less straightforward, and probably does not occur via termolecular reactions with H_2O . Although they are less strongly bound, formation of clusters with more abundant species such as N_2 , in reactions such as

is more likely. Although the density of CO_2 is much smaller than that of N_2 , it is expected to have a larger NO^+ affinity than

N_2 , and to form cluster ions either by a switching reaction with $NO^+(N_2)$ or by three-body association reactions:

The weakly bound cluster ions $NO^+(N_2)$ and $NO^+(CO_2)$ may then be transformed to the more stable hydrates via switching reactions with water, such as

where *X* is either N_2 or CO_2 . Because H_2O has a permanent dipole moment, the NO^+ cluster $NO^+(H_2O)$ is more strongly bound than that with N_2 or CO_2 , but its dissociation energy is still less than 0.8 eV. The NO^+ affinities of neutral species are expected to be correlated with the proton affinities, which are shown in Table 3. NO^+ clusters such as $NO^+(H_2O)(X)$ may be stabilized by the presence of a species *X*, which denotes any of a number of abundant or trace mesospheric species. The most stable clusters are those for which the clustering molecule *X* has a permanent dipole moment. Many of the NO^+ cluster ions are weakly bound, and dissociate collisionally. This tendency leads to a strong temperature dependence for some of the reactions, and of the NO^+ hydration scheme.

The formation of clusters is much more likely at temperatures near and below 200 K than at room temperature. The equilibrium constants for cluster formation reactions increase by orders of magnitude from 300 to 200 K. The NO^+ water cluster ion, $NO^+(H_2O)_3$, may react with H_2O in a switching reaction to produce a proton hydrate:

Small $NO^+(H_2O)_n$ clusters may undergo unimolecular decay via

For large *n*, the NO^+ clusters are more likely to decay via:

Only the larger proton hydrates are efficiently produced from NO^+ .

A schematic diagram of possible *D*-region positive ion chemistry is shown in Figure 13. Recent model calculations of altitude profiles of the most important positive ions are shown in Figure 14. It should be noted that, in addition to the transformation reactions discussed above, cluster ions are subject to competing loss processes such as photodissociation, collisional dissociation, and DR. Large loosely bound cluster ions are characterized by large DR coefficients, which are of the order of $5 \times 10^{-6} \text{ cm}^3 \text{ s}^{-1}$. A collection of rate coefficients for positive cluster ions involved in *D*-region chemistry has been compiled by Kopp (1996).

The density of free electrons become less than that of negative ions below an altitude of about 70–75 km during the daytime, and about 75–80 km at night. The formation of negative ions begins with the pressure-dependent three-body attachment of an electron to O_2

and to a lesser extent by dissociative attachment

CO ₃	CO ₃ ⁻	3.26
Cl	Cl ⁻	3.6
HCO ₃	HCO ₃ ⁻	3.67
NO ₃	NO ₃ ⁻	3.9

From Lias, S.G., Bartmess, J.E., Liebman, J.F., Holmes, J.L., Levin, R.D., Mallard, W.G., 1988. Gas phase ion and neutral thermochemistry. *Journal of Physical Chemistry Reference Data* 17 (Suppl. 1) and from NIST Chemistry Webbook (webbook.nist.gov).

Further transformation of these negative ions competes with photodetachment

and associative detachment

If they are not destroyed, these initial negative ions undergo a series of reactions that produce more stable negative ions, which are those that are formed from parent neutrals that have larger electron affinities. Selected electron affinities are presented in **Table 5**. Transformation reactions include three-body association, in such reactions as

and

electron-transfer reactions such as

and atom abstraction reactions including

and

These reactions transform the initial negative ions into a plethora of intermediate ions, ending probably in the terminal ions NO₃⁻, CO₃⁻, Cl⁻, and HCO₃⁻, the parent neutrals of which have very large electron affinities.

Termolecular clustering reactions of negative ions may also occur, in such reactions as

Negative ions may also be destroyed by mutual neutralization with positive ions, the rate coefficients for which are of the same

order as DR coefficients, $\sim 10^{-7} \text{ cm}^3 \text{ s}^{-1}$. The terminal ions tend to have longer chemical lifetimes and larger densities than the intermediate ions. Negative ion chemistry is highly dependent on pressure and temperature, and on the densities of minor photochemically produced constituents in the atmosphere, especially O and O₃. Since solar fluxes play a role in electron detachment, there is a strong day–night asymmetry. Compilations of negative ion reactions relevant to the D region have been presented by Kopp (1996) and by Ikezoe et al. (1987).

Synopsis

Knowledge about the isotopic composition of a range of atmospheric trace gases has proven useful in better defining their sources and chemical modification, including phase transitions in the case of water vapor. Information on the nomenclature, relevant processes like isotope fractionation is given and the better known applications are reviewed.

Introduction

Chemical reactions, phase transitions, and processes like diffusion induce small but measurable changes in the stable-isotope abundances of the elements in atmospheric gases and in aerosol. These natural variations do not affect chemistry or transport but their investigation deepens our understanding of certain atmospheric processes. The underlying principles are that different sources of trace gases have different isotopic compositions ('signatures,' or 'fingerprints'), and that the isotopic compositions of trace substances are changed by chemical and physical sink processes. Application of isotopic analysis in atmospheric chemistry has revealed a class of new isotope effects, which stimulates fundamental research. Analytical progress in mass spectroscopy allows very small quantities of substances to be analyzed rapidly. Moreover, the precision, which lies at the heart of resolving the intrinsically small isotope effects, is continuously increasing, reducing under special conditions the uncertainties in the isotopic ratio determinations to below 10 ppm. Progress in optical spectroscopy allows orders of magnitudes more measurements to be carried out. Also laboratory research keeps pace with the developments and for an increasing number of atmospherically relevant reactions, isotope effects are being measured and predicted by theoretical models. This facilitates new applications of isotope analysis in atmospheric sciences, while at the same time the links between the atmosphere and the biosphere can be better studied using these isotope tools.

Notation and Nomenclature

With the exception of hydrogen, variations in stable-isotope ratios occurring in nature usually amount to only several percent. Therefore, the isotope abundances of a particular element in a given compound are expressed as per mil (10^{-3}), or sometimes even per meg (10^{-6}) on a relative scale that is defined by one or more standard reference materials. For a given sample (SA), the isotopic value relative to the standard material (ST) is given in parts per thousand (per mil, or ‰). Using carbon-13 as an example with $R = n(^{13}\text{C})/n(^{12}\text{C})$, eqn [1] gives the relative isotopic composition.

$$\delta^{13}\text{C} = (R_{\text{SA}}/R_{\text{ST}} - 1) * 1000 \quad [1]$$

This definition is based on the ratio of the minor to the most abundant isotope. It excludes the use of molecular

ratios, so that, for instance, $\delta^{13}\text{CH}_4$ is not defined and the notation $\delta^{13}\text{C}(\text{CH}_4)$ is used. For the deuterium content of a sample of methane the appropriate equation corresponding to eqn [1] is used. The molecular ratio in the sample, $(\text{CDH}_3)/(\text{CH}_4)$, will be four times larger. Given the low abundance of deuterium, the fraction of methane molecules with two or more deuterium atoms is negligible. The word 'isotopologue' (isotopic analogue) denotes the isotopically substituted molecule, accordingly $^{13}\text{CO}_2$ and $^{14}\text{N}^{15}\text{N}$ are isotopologues of CO_2 and N_2 . The word 'isotopomer' (isotopic isomer) is used to indicate that isotopic substitution is at another site in the molecule, for instance for nitrous oxide we have the two isotopologues $^{15}\text{N}^{14}\text{NO}$ and $^{14}\text{N}^{15}\text{NO}$.

For any two reference materials A and B, the conversion for a sample X is made according to eqn [2].

$$1 + \delta_{\text{A}}(\text{X}) = (1 + \delta_{\text{B}}(\text{X})) / (1 + \delta_{\text{B}}(\text{A})) \quad [2]$$

For mixing a molar fraction f having a delta value δ_{a} into a reservoir with a background value of δ_{b} , the resulting isotopic composition will be given in good approximation by eqn [3].

$$\delta_{\text{r}} = f\delta_{\text{a}} + (1 - f)\delta_{\text{b}} \quad [3]$$

For convenience, Table 1 gives the isotopic abundances of the elements most often analyzed in atmospheric compounds. Reference materials for reporting isotopic composition are available from the International Atomic Energy Agency (IAEA). The International Union of Pure and Applied Chemistry have issued in 2011 a modified periodic table of the elements. This new table gives for a number of elements (H, Li, Be, B, C, N, O, Si, S, and Cl), instead of the standard atomic weights of these

Table 1 Minor isotope abundances

Element	Minor isotopes	Abundance (%)	Main reference materials
H	^2H or D	0.15	V-SMOW ^a
C	^{13}C	1.11	V-PDB ^b

elements, ranges of values. For instance, for sulfur in natural terrestrial compounds the standard atomic weight lies between 32.05 and 32.08. The differences in stable-isotope composition are due to isotopic fractionation, mainly caused by the role of mass differences in a variety of chemical and physical processes. When isotopic fractionation occurs, the fractionation factor α is defined as the isotopic ratio in one compound or phase relative to that of the other. No strict convention is in operation. For instance, water vapor is often assayed relative to the liquid, and $\alpha < 1$ (i.e., depletion). The accompanying fractionation constant ϵ is defined as $\alpha - 1$. For chemical reactions kinetic isotope effect (KIE) is often used instead of the conventional α . For KIE, the fractionation factor is the ratio between the reaction rate constants for the minor and major isotopomers, or vice versa.

Measurement

Measurement of isotopic ratios for the elements mentioned above is based on mainly two principles. One is mass spectrometry. This technique can deal with smallest amounts, down to subnanomolar quantities, which is important as we deal with atmospheric trace gases. Also the highest precision is achieved by mass spectrometry. The analytical principle is mostly electron impact ionization, ion acceleration, magnetic separation of the isotopic masses followed by ion current measurement using Faraday collectors. Conversion of measured ratios to the appropriate reference material is basically done using eqn [2], after corrections, especially ion current corrections, have been made. For instance for CO_2 , mass 45 represents a combination of the isotopologues $^{13}\text{C}^{16}\text{O}^{16}\text{O}$ (about 1%) and $^{12}\text{C}^{17}\text{O}^{16}\text{O}$ (twice about 0.04% because of the two O atoms). To make the correction, one needs information about the $^{17}\text{O}/^{16}\text{O}$ ratio, which is mostly estimated from the respective $^{18}\text{O}/^{16}\text{O}$ ratio (the ratio of mass 46 ion beam current to that of mass 44). Aerosols or trace gases can be oxidized to give CO_2 , which is purified by gas chromatography and injected in a flow of helium into the mass spectrometer. In case very high precisions are required, the gas to be analyzed, for instance CO_2 or SF_6 in case of sulfur isotope analysis, has to be introduced in micromole amounts using vacuum transfer followed by repeated comparisons with a reference gas.

The other measurement principle is based on optical absorption spectroscopy. When using high-resolution spectroscopy, the differences in optical spectra of isotopologues and isotopomers can be resolved. The challenge of the extremely low abundance – for instance N_2^{18}O is only 0.2% of 380 ppbv (N_2O mixing ratio) – is dealt with by using very long absorption path lengths and the cavity ring down method. These optical techniques are extremely powerful for atmospheric applications as they can provide real time, continuous *in situ* data. Also sample pretreatment is in many cases not required at all. Development to increase the precision of these optical techniques is ongoing.

Kinetic and Equilibrium Isotope Effects

A distinction is made between kinetic and equilibrium isotope effects. Using water vapor in contact with water in an enclosed

volume, the depletion of the vapor in D and ^{18}O can be calculated on the basis of the vapor pressure differences. When water evaporates through the stomata in plant leaves into dry air, the additional kinetic effect caused by the diffusion speed differences of H_2^{18}O and H_2^{16}O in air increases the overall fractionation strongly. When CO_2 is in oxygen isotopic equilibrium with H_2O for which carbonate and bicarbonate formation is necessary, its ^{18}O content at 25 °C is 41‰ above that of the water. This effect can be calculated like most other (thermodynamic) equilibrium effects, using statistical mechanics and the partition function.

Kinetic isotope effects are common in chemical reactions. The heavier isotopes have a lower zero point energy which leads to stronger intramolecular bonding. Generally, heavier isotopologues molecules react more slowly. Calculating kinetic isotope effects is more complex and transition state theories with a range of refinements, including tunneling effects, are often used. For the atmospherically relevant reaction between chlorine radicals (Cl) and CH_4 , calculations are based on the intermediate complex Cl-HCH_3 . The theory and experimental results do not always conform. The kinetic isotope effects for all D-based carbon-12 isotopomers of methane are shown in Table 2. These are the largest effects known, although in atmospheric applications only reactions with CH_4 and CDH_3 play a role. The heavier isotopologues react slower, which is a normal isotope effect. A notable exception where the substitution with a heavier isotope does not reduce, but increases reaction speed is the well-known reaction $\text{CO} + \text{OH}$, in which C^{18}O reacts faster than C^{16}O . The various isotope fractionation processes of relevance to atmospheric processes are shown in Table 3. For the biogeochemical cycles on N_2O , nitrates, CH_4 , H_2 , and other atmospheric trace compounds, not only gas-phase reactions play a role, but also enzymatic processes.

Biological/enzymatic processes	Nitrification/denitrification

Mass-Independent Fractionation

Stable-isotope studies dealing with atmospheric trace gases have revealed one or more types of fractionation processes that are not completely understood and have been pooled under the name ‘mass-independent fractionation’ (MIF). The rationale for this name was that such an effect, a very large one, was first observed for ozone (O_3), and became attributed to molecular symmetry effects, totally independent of mass. Retrospectively, the name is an unfortunate choice and is at times used along with the expression ‘anomalous fractionation.’ We emphasize that the effect was discovered using oxygen isotopes. There was a strong discrepancy measured in the abundance of ^{17}O in ozone relative to that expected on the basis of a simple relationship between ^{17}O and ^{18}O fractionation. Thus by virtue of oxygen having three stable isotopes, the effect became so clearly detectable. Figure 1 shows the relationship between $\delta^{17}O$ and $\delta^{18}O$ for a wide range of substances. The slope of the mass-dependent fractionation line thus defined is close to 0.52. The theoretical basis for this correlation for a range of physical and chemical processes is well understood. For instance, the equilibration constant for an isotope exchange reaction is proportional to the vibrational frequencies, and therefore the reciprocal masses. For diatomic molecules for O isotopes (^{18}O , ^{17}O , and ^{16}O) one obtains simply $(1/16 - 1/17)/(1/16 - 1/18) = 0.53$. In fact, because of this omnipresent strict mass dependence, almost no attention was paid to the analysis of ^{17}O in oxygen-containing compounds for several decades. Atmospheric research has

Figure 1 The $\delta^{18}O$ and corresponding $\delta^{17}O$ values for some important reservoirs showing mass-independent fractionation effects as deviations from the ‘mass dependent’ fractionation line of slope 0.52. This slope is however not exactly the same as it depends on the fractionation processes involved, nearly all of which are strictly mass dependent. Note that molecular oxygen has a small negative value $\Delta^{17}O = -0.15\text{‰}$, not visible on this scale. All mass-independent effects shown are due to the anomaly in ozone, with exception of CO which obtains most of its MIF from the reaction $CO + OH$ and a smaller part from the formation of CO by the reaction of ozone with unsaturated hydrocarbons such as isoprene.

changed this and MIF has been detected for O_3 , CO_2 , CO , N_2O , H_2O_2 , SO_2 , and even atmospheric molecular oxygen discussed later. Nearly all of these effects can be traced back to the large anomaly in ozone. A measure for MIF is the deviation in ^{17}O content, in approximation expressed as $\Delta^{17}O = \delta^{17}O - 0.52 \delta^{18}O$.

Atmospheric Applications

General

Isotope effects do not significantly affect atmospheric chemistry. Not only are fractionation effects generally small, but also the abundances of the minor isotopes are low. Even though the isotope effects for deuterium may be large because of the large relative mass difference, its low abundance (Table 1) excludes effects on chemistry. For chlorine, the less-abundant isotope is still rather abundant, but in this case, fractionation effects of only a few percent do not impact on chemistry. The corollary is that isotope effects may give useful information but have no impact. Given a certain atmospheric trace gas, isotopic variations are due to two factors. One is the isotopic composition of its sources. In principle, the relative source strengths can be calculated using eqn [3], provided there are only two isotopically distinct sources. The other factor, which disturbs this simple source-based picture, is isotope fractionation in the removal of the gas, be it deposition or atmospheric chemistry. For an isolated, well-mixed amount of gas being depleted by a loss process (e.g., reaction with OH or photolysis), the isotopic composition will evolve in time according to a Rayleigh distillation process. Using m/m_0 as the ratio of the actual to the initial mixing ratio, eqn [4a] or [4b] apply.

$$\delta + 1 = (m/m_0)^{(1-1/\alpha)} \quad [4a]$$

$$\delta \approx (1 - 1/\alpha) \ln (m/m_0) \quad [4b]$$

Ozone, O_3

In situ isotopic measurements of stratospheric ozone were obtained using balloon-borne mass spectrometry. Moreover cryogenic air sample collection was used. Ozone is formed via $O(^3P) + O_2 + M \rightarrow O_3 + M$ and it has a remarkable isotopic composition throughout the atmosphere. It is considerably enriched in ^{18}O relative to its immediate precursor molecular oxygen by 70–110‰ and surprisingly, by almost the same degree in ^{17}O . No other substance on Earth has found to have such high and anomalous oxygen isotope enrichment. As we will explain later, MIF in ozone affects the isotopic composition of a host of other trace gases that are linked to the ozone cycle. The causes for the oxygen isotope anomaly in ozone are not fully understood. Theoretical work by R.A. Marcus and coworkers published in 2011 deals for instance with Coriolis coupling as a source of non-RRKM effects in the ozone molecule. Also laboratory studies are in progress. Part of the ozone enrichment is linked to the reaction constants for the formation of the various ozone isotopomers and isomers. Table 4, based

Table 4 Relative reaction rates for the formation of ozone from $^{16}\text{O}(\text{O})$, $^{17}\text{O}(\text{P})$, and $^{18}\text{O}(\text{Q})$

Reaction	Relative rate

P + QQ	1.31
Q + QQ	1.03

on laboratory experiments, shows the surprising fact that isotopic substitution leads to enormous differences in reaction rate constants.

The analysis of the isotopic composition of stratospheric, and particularly tropospheric ozone is extremely difficult, and few data are published. Most work concentrate therefore on laboratory studies, on the formation of ozone, its behavior on surfaces, temperature and pressure dependence, and so on. An interesting venue for atmospheric measurement is however available, namely the reaction of ozone with a compound that can be subsequently analyzed. One can think of silver or a sulfide as reactant. Interestingly, such a technique gives the $^{17}\text{O}/^{16}\text{O}$ and $^{18}\text{O}/^{16}\text{O}$ ratio for the terminal oxygen atom in ozone. There are indications that the enrichment at this site is higher than for the central oxygen atom position.

Carbon Dioxide, CO_2

Troposphere

Quantifying fluxes of atmospheric CO_2 between the Earth's carbon reservoirs is a major task and of great importance. Therefore, isotopic analysis of CO_2 has continuously evolved since the first applications by Keeling and Craig in the 1950s. Currently, ^{13}C and ^{18}O analyses are carried out on CO_2 extracted from air sampled in flasks of the NOAA-ESRL network. The combustion of fossil fuel and deforestation have lead to a decrease in $\delta^{13}\text{C}$ from a preindustrial value (relative to V-PDB) of about -6 to about -8‰ in 2010. Photosynthesis favors the uptake of $^{12}\text{CO}_2$ over that of $^{13}\text{CO}_2$, by which plant organic matter is depleted. The ^{13}C value of fossil fuel carbon is close to the values of the original vegetation and aquatic organisms millions of years ago, and is around -27‰ . The ^{13}C equilibrium between ocean bicarbonate and atmospheric CO_2 has kept the values for the biota at nearly the same level, but the sudden release of enormous amounts of fossil fuel-derived carbon disturb the equilibrium. One application of ^{13}C is to distinguish between CO_2 uptake by the land biota and by the oceans. The overall activity of the biosphere, which is dominated by the Northern Hemisphere biota, induces a seasonal cycle of up to 1‰ at the surface at mid to high latitudes. The seasonal minimum is in spring when CO_2 emissions from respiration, oxidation, and fossil fuel burning have peaked. A useful application of $\delta^{13}\text{C}(\text{CO}_2)$ has been the identification of

a large Northern Hemispheric terrestrial carbon sink in 1992 and 1993. When Charles Keeling, who pioneered high precision CO_2 concentration measurements, plotted $\delta^{13}\text{C}$ against the inverse of the CO_2 concentration of air samples, basically applying eqn [3], what he established is known as the Keeling plot. In the plot, the extrapolation to infinite CO_2 concentrations provides the ^{13}C isotopic composition of the admixing source.

In contrast to ^{13}C , $\delta^{18}\text{O}(\text{CO}_2)$ is determined by the isotopic exchange of CO_2 with the main water reservoirs on Earth. The effect for ^{13}C being a mere source-sink effect, for ^{18}O the gross fluxes of CO_2 into and from plant leaves dominate the isotopic composition. The exchange of ^{18}O in cloud droplets is in comparison negligible. Exchange with water vapor is excluded as the formation of carbonate or bicarbonate is necessary. However, exchange with soil water, the mentioned leaf water, and ocean water is important. In this, CO_2 strives toward isotopic equilibrium accompanied by a temperature-dependent enrichment of about 40‰ . Accordingly, the $\delta^{18}\text{O}$ value of CO_2 is close to 40‰ (Vienna-Standard Mean Ocean Water (V-SMOW)). Note that the standard V-SMOW- CO_2 (CO_2 in isotopic equilibrium with V-SMOW at 25 °C) is often used, thus giving a value of near 0. Because leaf water is enriched owing to the equilibrium and kinetic isotope effects accompanying stomatal evaporation, CO_2 in equilibrium with leaf water is more strongly enriched. The ^{18}O isotope effect of emissions of CO_2 from fossil fuel combustion has only a local influence in relative close proximity to the sources. Internal combustion engines produce CO_2 with ^{18}O values close to that of atmospheric CO_2 . The combustion of coal gives values closer to 0, whereas burning gives a range of values in between. When CO_2 from two sources is mixed, each with a given $^{18}\text{O}/^{16}\text{O}$ ratio, one can calculate the resulting (very low) abundance of $\text{C}^{18}\text{O}^{18}\text{O}$. This calculated ratio does not necessarily correspond with the real $\text{C}^{18}\text{O}^{18}\text{O}$ ratio, because it would require scrambling of ^{18}O between the CO_2 molecules, which does not occur. The deviations from the statistically expected random distribution of isotopomers can be measured by carrying out what is named 'clumped isotope analysis.' By taking CO_2 and heating it to high temperatures in a quartz vial, the distribution of ^{13}C , ^{17}O , and ^{18}O is randomized, and this situation can be frozen by rapid cooling. By comparing the relative abundance of $^{13}\text{C}^{16}\text{O}^{18}\text{O}$ of a CO_2 sample to that of heat-treated CO_2 with great precision using the ion beam of the rare mass 47, deviations have been measured. There are, up to date, few atmospheric applications mainly due to the difficulty of such measurements.

Stratosphere

The seasonal variations of $\delta^{13}\text{C}$ and of CO_2 mixing ratios propagate with delay while being attenuated into the stratosphere. This allows accurate stratospheric measurements to be used as a timer. The most important aspect from the isotope point of view is however that CO_2 can interact with ozone which has this anomalous isotopic composition. The reactions involved are $\text{O}_3 + h\nu \rightarrow \text{O}_2 + \text{O}(^1\text{D})$. The excited oxygen atom can, if not quenched before, form a short-lived complex

CO_3 which enables isotopic exchange, according to $\text{O}(^{17}\text{O}) + \text{CO}_2 \rightarrow (\text{CO}_3)^* \rightarrow \text{O}(^{17}\text{O}) + \text{CO}_2$. In the stratosphere $\Delta^{17}\text{O}(\text{CO}_2)$ can reach values of 17‰ . By this $\Delta^{17}\text{O}$ is a tracer for CO_2 of stratospheric origin. In the troposphere this signal is diluted by CO_2 that has no anomalous ^{17}O content. It is speculated that measurement of $\Delta^{17}\text{O}$ can help to determine the rate of oxygen isotope exchange of CO_2 with the hydrosphere.

Water, H_2O

Troposphere

Because of the many roles of atmospheric water through latent heat, cloud formation and albedo, heterogeneous chemistry, and the radiation budget, various efforts are made to use isotopic analysis. The IAEA coordinates the global monitoring of the isotopic composition of precipitation for hydrological applications (isotope hydrology). There are large seasonal and geographical differences. Water evaporating from the oceans is depleted, but the condensing water is again enriched relative to the vapor. With increasing distance into the continents, D and ^{18}O decrease (distance effect) following the mentioned Rayleigh fractionation (eqn [4b]). With increasing latitude and decreasing temperatures, continued precipitation causes further depletion. In Antarctica, δD can be as low as -400‰ and $\delta^{18}\text{O}$ reaches -50‰ . Isotopic analysis of ice cores is one of the main tools in paleoclimatology. Global precipitation D and ^{18}O isotope values define the 'meteorological water line' $\delta\text{D} = 8\delta^{18}\text{O} + 10\text{‰}$. Hailstones have been assayed layer by layer for study of their formation process. Increasing attention is being paid to tropospheric water vapor analysis. Not only the worsening situation concerning water supplies, but also climate change research drives large efforts to obtain and better use isotopic information of atmospheric water. Isotopic values are included in certain models that incorporate the hydrological cycle. The advent of the *in situ* optical determination of δD and $\delta^{18}\text{O}$ in water vapor heralds great progress for these important applications.

In the section [Mass Independent Fractionation](#), the general mass-dependent line of slope 0.52 was mentioned. This slope varies slightly depending on the molecules and fractionation processes that are involved. B. Luz and E. Barkan have by means of extremely precise measurements established the Global Meteoric Water Line, which is given by $\ln(\delta^{17}\text{O} + 1) = 0.528(\delta^{18}\text{O} + 1) + 0.000033$ ($R^2 = 0.99999$). The meteoric waters have a small excess of ^{17}O relative to ocean water. Also diffusion of water vapor into plant leaves will lead to deviations that can be used to study certain processes.

Stratosphere

In the stratosphere, gas-phase chemical interactions affect the isotopic composition. Through cooling and concomitant condensation, water vapor reaching the tropopause attains values of $\delta\text{D} = -670\text{‰}$ and $\delta^{18}\text{O} = -82\text{‰}$. During transport into the middle atmosphere, isotope exchange and addition of H_2O from methane oxidation take place. Exchange of oxygen is via the HO family of reactions involving oxygen and ozone.

These processes enrich the isotopically depleted vapor imported from the troposphere. Above 40 km, δD reaches about -400‰ and stays constant at that level. $\delta^{18}\text{O}$ increases by as much as 100‰ . There is a clear deviation from the meteoric water line. Furthermore, stratospheric H_2O obtains MIF largely from O via $\text{H} + \text{O}_3 \rightarrow \text{OH} + \text{O}_2$ and the subsequent hydrogenation of OH. The oxygen isotope exchange between OH and H_2O has a rate constant of $6 \times 10^{-17} \text{ cm}^3 \text{ s}^{-1}$ at 250 K and plays no significant role. $\delta^{17}\text{O}$ increases from 0 at the tropopause to 10‰ at 40 km.

Methane, CH_4

Atmospheric methane with its many categories of sources forms a classical example of stable-isotope applications. Its isotopic composition, i.e., δD and $\delta^{13}\text{C}$, and that of its sources are shown in [Figure 2](#). The depletion in ^{13}C is largely the result of the fractionation in the formation of CH_4 by bacterial processes as well during digestion in ruminant, as in rice paddies and wetlands. Deuterium shows a similar pattern, but has a large range. The difference between the input from the combined sources and the actual atmospheric composition is caused by the isotopic fractionation in the removal reaction $\text{CH}_4 + \text{OH}$. The large effect for deuterium is apparent. Also, the small soil sink isotopically enriches the methane that is left in the atmosphere. Despite the considerable spread in the source values, inverse modeling using the isotopic composition has helped to further constrain the methane budget. Both $\delta^{13}\text{C}$ and δD show seasonal cycles with amplitudes of approximately 0.2 and 4‰ respectively, depending on latitude which can be resolved with difficulty. There are presently few data on deuterium available, but the advances in isotope mass spectrometry that have been mentioned change this. Interannual variations in the Southern Hemisphere have been associated with biomass burning. Moreover, in the Southern Hemisphere

Figure 2 Overview of the ^{13}C and deuterium (^2H) isotope ratios of the main methane sources. The arrow indicates the kinetic isotope effect responsible for the differences between the isotopic composition of the combined sources and that of the atmospheric inventory.

Table 5 Kinetic isotope fractionation factors (KIE) for reaction with CH₄ at 296 K

	¹³ C	D
OH	1.004 ^a	1.294 ^b
Cl	1.065	1.50
O(¹ D)	1.013	1.06

^aValues given for k_{12}/k_{13} .^bValues given for k_H/k_D .

small increases in $\delta^{13}\text{C}$ have been detected that were attributed to the reaction of Cl + CH₄. As Table 5 shows, this reaction has a characteristic large ¹³C kinetic isotope effect. The strong increase in atmospheric CH₄ has induced an isotopic disequilibrium in which the isotopic composition came closer to that of the averaged source. Analysis of CH₄ extracted from firm air reveals a clear minimum δD value about 75 years ago. After a weakening in the increase of CH₄ over the last decade, the equilibrium was approached more closely and δD increased again. Stratospheric chemistry produces large isotope changes in CH₄ because of the greater role of Cl and O(¹D) as sinks. Table 5 shows that O(¹D) has a large isotope effect, which was not expected on the basis of the rapid kinetics of this reaction. The isotopic composition of CH₄ in the stratosphere can be successfully modeled using a 2D model, incorporating the fractionation factors from Table 5. Such results are further used for calculating δD of H₂O and $\delta^{13}\text{C}$ of CO.

Hydrogen, H₂

Scientific interest in the D/H ratio of molecular hydrogen is increased due to the possible large-scale future use of H₂ as an energy carrier to replace fossil fuels. Releases of H₂ into the atmosphere could disturb the OH-based oxidative cycle and also lead to the production of additional H₂O in the stratosphere. Given that the distribution of hydroxyl, OH, and the KIE of H₂ + OH are well known, the uptake of H₂ by soils, which introduces much less fractionation, can be assessed using δD measurements. The Northern Hemisphere has lower H₂ mixing ratio, the Southern Hemisphere has higher $\delta\text{D}(\text{H}_2)$ values. With OH not showing major N–S differences, the effect of the soil sink with much smaller fractionation is evident. Few laboratories embarked on such measurements because of the elaborate procedure of separating H₂ from air. Nevertheless, another issue is that across the tropopause H₂ mixing ratios changes little. The reason is production of H₂ from CH₄ while in contrast to the troposphere the (large) soil sink is missing. In all these, the D/H ratio of H₂ from the photolysis of HCHO has undergone close scrutiny. It is clear that D/H analyses considerably improve H₂ budget estimates and modeling of D has been fully developed. A difficult issue is the D/H ratio of HCHO and that of H₂ from its photolysis.

Hydrocarbons, Formaldehyde, Methyl Chloride, and Other Trace Gases

The recent introduction of coupled gas chromatography isotope mass spectrometry has allowed the analysis of nanomole

amounts of substances, bringing the low-abundance trace gases within reach of isotopic analysis. Values obtained for ethane, ethene, and propene in background air in New Zealand yielded $\delta^{13}\text{C}$ values of -22 to -29‰ , which is typical for organic matter. Methyl chloride was strongly depleted at -43.5‰ . Samples collected south of Japan, between 5 and 35° N, showed the following $\delta^{13}\text{C}$ values: ethane, propane, *n*-butane, *n*-pentane, *i*-butane, and *i*-pentane between 30 and -23‰ ; ethylene and propylene between about -30 and -10‰ ; acetylene between -20 and -2‰ ; and methyl chloride between -40 and -30‰ . There is only one major study on formaldehyde, HCHO, and it deals with urban air. Bearing in mind that even formaldehyde concentration measurements are rare, measuring its isotopic composition is a daunting task indeed. Over a wide range of concentrations $\delta^{13}\text{C}$ values were close to that of organic matter, namely -28‰ . In remote air one could expect HCHO derived from CH₄ oxidation to lead to lower δ values. At the same time δD values ranged from -300 to $+200\text{‰}$ and were weakly anticorrelated with concentration. If considered worthwhile, years of work are needed to make more HCHO isotope measurements. An extreme application was the detection of a 20‰ enrichment of ³⁷Cl in CF₂Cl₂ at stratospheric altitudes where its mixing ratio had dropped from about 550 to 100 pmol mol⁻¹ due to photolysis.

Carbon Monoxide, CO

The shorter lifetime of CO results in considerable concentration and isotopic changes (Figure 3). Concerning the source signatures, CO from high-temperature combustion processes adopts the $\delta^{18}\text{O}$ value of atmospheric oxygen (about $+23.5\text{‰}$) without much fractionation. This gives a useful clear signal for the technological source. Also distinctive is the low $\delta^{13}\text{C}$ value of CO derived from CH₄ oxidation. This value is believed to be about -51‰ , composed of the -47‰ of CH₄ further lowered by the kinetic fractionation of -4‰ in the reaction CH₄ + OH (Table 5). There are problems in closing the isotope budget for ¹³CO in the Southern Hemisphere using this information, because atmospheric $\delta^{13}\text{C}(\text{CO})$ values rarely fall below -32‰ . One has to assume that additional isotope fractionation occurs in the formation of CO from the photolysis of formaldehyde. The yield of CO from CH₄ + OH may be different throughout the troposphere, but low values are not likely. For ¹³C there is a pressure effect. Its KIE maximizes at 5‰ at 1013 hPa, and turns into a negative effect at altitudes above a pressure of 300 hPa. The annual average $\delta^{13}\text{C}$ value in the Southern Hemisphere is approximately -29‰ ; in the midlatitude Northern Hemisphere it is -27‰ . The annual cycles are dominated by the CH₄ source effect and not by the KIE of CO + OH. For ¹⁸O there is a negative isotope effect of nearly -10‰ , almost independent of pressure. Generally, the farther away from CO sources, the more negative the $\delta^{18}\text{O}$ becomes, reaching -10‰ in the lowermost stratosphere. There are only few stratospheric data for CO, but air samples collected during ozone hole conditions in the Antarctic lowermost stratosphere yielded CO with $\delta^{13}\text{C}$ as low as -43‰ . Modeling confirms that CO from CH₄ + Cl causes such anomalous low values.

Another application of the large KIE in CH₄ + Cl is the estimation of free chlorine during Arctic low ozone events at

Figure 3 Overview of the ^{13}C and ^{18}O isotope ratios of the main carbon monoxide sources. The arrow indicates the kinetic isotope effect. Observational values for some Northern Hemisphere locations are shown. The spread in the data is mostly due to the seasonal cycle.

the surface. Small downward excursions in $\delta^{13}\text{C}(\text{CO})$ were observed during such events proving the presence of Cl atoms.

After MIF had been detected for O_3 and CO_2 , it also was discovered in CO. MIF in CO has two causes. One is that unsaturated organic compounds react with O_3 . CO from these reactions is a small source of CO enriched in ^{17}O and ^{18}O and exhibiting MIF derived from O_3 . However, the main cause lies in the important reaction $\text{CO} + \text{OH} \rightarrow \text{CO}_2 + \text{H}$. Assuming for the moment that C^{18}O reacts 10‰ faster than C^{16}O , C^{17}O should react about 5‰ faster if the normal mass-dependent fractionation applies. In contrast, C^{17}O reacts nearly as rapidly as C^{16}O . This then results in an excess of ^{17}O in atmospheric CO. There is no complete theoretical explanation for the cause of MIF in $\text{CO} + \text{OH}$, but work by R.C. Markus and coworkers is in progress. Because all major CO sources are mass dependent, $\delta^{17}\text{O}(\text{CO})$ is a unique signal indicating the ‘aging’ of CO by reaction with OH. Atmospheric chemistry transport models have been developed that incorporate the isotope effects of CO and its precursors.

Nitrous Oxide, N_2O

Despite its long lifetime and concomitant small isotopic and abundance variability, the isotopic composition of N_2O is being studied intensively. For this greenhouse gas with a variety of sources closely linked to human activities and having a long lifetime, isotope information is valuable. The $\delta^{15}\text{N}$ and $\delta^{18}\text{O}$ values of tropospheric N_2O show little scatter around approximately 7 and 21‰ relative to atmospheric N_2 and O_2 , respectively. The main sources of N_2O are based on microbial nitrification and denitrification in soils and the ocean, and are generally depleted relative to the atmosphere. The range of δ values is considerable. Soil gases form the

most depleted source type, with averages of about -13 and 10 ‰, respectively. A source identified with enrichment was N_2O from denitrification in upwelling deep water in the Arabian Sea. Enriched N_2O was also found in the Pacific. These sources do not account for the atmospheric enrichment. The enrichment of atmospheric N_2O has been explained on the basis of its main stratospheric sink, i.e., photolysis. N_2O that escapes photolysis and is reimported into the troposphere causes enrichment relative to the average sources. Theory and experiment of photolysis show a qualitative agreement. Photolysis experiments over the entire range of wavelength of interest still have to be performed. Analysis of stratospheric N_2O samples confirms that enrichment increases with altitude. Increased interest in N_2O was sparked by the awareness that in this linear molecule, NNO, fractionation through photolysis is not identical for the two different N atoms.

Instrumental innovation in mass spectrometry now allows the detection of the isotopic ratios for both positions using only small amounts of sample. Also spectroscopic techniques allow such determinations. Figure 4 shows the result of N_2O photolysis for ^{15}N at 193 nm. The fractionation factors for $^{15}\text{N}^{14}\text{NO}$ and $^{14}\text{N}^{15}\text{NO}$ are 10.9 and 35.7‰ respectively. Thus $^{14}\text{N}^{15}\text{NO}$ is less likely to be photolyzed. The same applies for $^{14}\text{N}^{14}\text{N}^{18}\text{O}$, for which at this wavelength the fractionation factor is 17.3‰. For the other important stratospheric reaction, $\text{O}(^1\text{D}) + \text{N}_2\text{O}$, only few data are available. Possible gas-phase sources of N_2O have been proposed in the literature, and the occurrence of MIF, albeit at a low level ($\delta^{17}\text{O} \approx 1$ ‰), has intensified this interest. No confirmation has been provided, and the cause of MIF in N_2O , if a real effect, remains unknown. In the meantime the intramolecular site preference of ^{15}N fractionation in tropospheric N_2O has been determined by careful FTIR analyses to be 19.8‰.

Figure 4 A Rayleigh type of plot for the change in the ^{15}N isotopic composition of N_2O subjected to photolysis at 193 nm. The enrichment for $^{14}\text{N}^{15}\text{NO}$ is considerably larger than for $^{15}\text{N}^{14}\text{NO}$.

Molecular Oxygen, O_2

In view of the sheer size of this reservoir, no usable isotope effects were originally contemplated to occur. Notwithstanding, it has been established that even atmospheric oxygen itself possesses a small degree of MIF $\Delta^{17}\text{O} = -0.15\text{‰}$, which offers interesting applications. The ^{18}O isotopic enrichment of O_2 relative to ocean water (V-SMOW) is about 23.5‰ . The cause for this enrichment is well understood (Dole effect). Respiration processes in plants and soils favor the use of the lighter oxygen isotopologues. In addition to this is that the leaf water in plants, which forms the substrate for the oxygen appearing in photosynthetic products, is enriched. These processes keep atmospheric oxygen enriched relative to the very large reservoir of terrestrial water. Because of this exchange between the large terrestrial water reservoir and atmospheric O_2 , its isotopic composition should be strictly mass-dependent. However, a very small fraction of O_2 is continuously converted to O_3 , which exhibits MIF. Thus a small excess of ^{17}O is continuously being withdrawn. In the stratosphere, this MIF signal is transferred from the O_3 pool via $\text{O}(^1\text{D})$ to become incorporated into CO_2 . The ensuing step in the process is that CO_2 reenters the troposphere, where it isotopically exchanges with H_2O at the surface. In this way, CO_2 loses its MIF signature continuously to the large reservoir of H_2O . Another process transferring MIF is the reaction $\text{O}(^1\text{D}) + \text{H}_2\text{O}$, which also leads to a net loss of ^{17}O . Both processes remove a small excess of ^{17}O from the O_2 reservoir. Given the long lifetime of atmospheric oxygen of roughly 1000 years, it acquires a deficit of ^{17}O , resulting in the value $\delta^{17}\text{O} = -0.15\text{‰}$. Although this value is small, there are applications in limnology and oceanography in which atmospheric oxygen can be distinguished from photosynthetic oxygen.

Aerosols

The oxidation of SO_2 by O_3 or H_2O_2 in the liquid phase leads to a small degree of MIF in atmospheric sulfates. This

can possibly be applied to trace the oxidation pathway of SO_2 . There is one report of SO_2 possessing MIF, for which the reason is not known. Sulfur isotope measurements on marine sulfate aerosol particles support the hypothesis that dimethyl sulfide can be a source of non-sea-salt sulfate. Sulfates remain widely analyzed for their isotopic composition with useful applications. Some research has also been dedicated to carbon but also chlorine isotopes in aerosols. Much work concerns nitrates. It has been shown that the oxygen in aerosol nitrates is mass independently fractionated. The responsible process is the important reaction $\text{NO} + \text{O}_3 \rightarrow \text{NO}_2 + \text{O}_2$. When this NO_2 is further oxidized, much of the ozone MIF signal is transferred to nitrate. The effect has been measured, and modeled, and interesting applications are in ice cores and the pathways of nitrates after deposition.

Synopsis

Chemical kinetics is the study of the rates of transformation of chemical compounds from reactant species into products. This article describes the basic principles of chemical kinetics. By means of atmospherically relevant reactions, fundamental concepts relating to rate coefficients, reaction order, the rate expression, reaction mechanisms, elementary reactions, third-body reactions, and steady-state concentration analysis are introduced. Physical descriptions of the rate coefficient (and its temperature dependence) are given, derived from both collision theory and statistical mechanics. Approaches for extracting rate parameters from experiments are addressed, with a focus on pseudo-first order kinetic studies and relative rate determinations. The article briefly outlines the basic principles, as well as the advantages and disadvantages, of the three most commonly used experimental techniques for studying reaction kinetics: flow tubes, flash photolysis and smog chambers. Spectroscopic methods for detection of reagents and/or products are also discussed.

Introduction

Chemical kinetics is the study of the rates of transformation of chemical compounds from reactant species into products. The rate of a reaction is defined to be the rate of decrease with time of the reactant concentration (in number of moles or molecules per unit volume) due to chemical reaction(s), or, equivalently, the rate of increase of the product concentration. In the atmosphere, chemical reactions typically involve free radicals, as reactants, products, or both. Free radicals are neutral fragments of molecules containing an unpaired electron and are generally very reactive. Some important atmospheric examples include OH, HO₂, HCO, CH₃, and CH₃O. Stable molecules such as O₃, NO, and NO₂ also contain unpaired electrons, which can influence their reactivity.

Principles of Chemical Kinetics

Overall and Elementary Reactions

The rate is expressed in terms of 1 mol of reaction, so rates of concentration change are normalized to the reaction stoichiometric coefficients, which give the number of moles of each compound appearing in the balanced chemical equation. Thus for the reaction [I], in which *a*, *b*, *c*, and *d* represent the stoichiometric coefficients for their respective compounds in the balanced chemical equation, the rate is defined by eqn [1].

$$\text{Rate} = -\frac{1}{a} \frac{d[A]}{dt} = -\frac{1}{b} \frac{d[B]}{dt} = \frac{1}{c} \frac{d[C]}{dt} = \frac{1}{d} \frac{d[D]}{dt} \quad [1]$$

This expression gives the phenomenological rate at which reactants A and B are transformed to products C and D. It contains no information concerning the mechanism of the reaction, nor does it have any predictive utility.

Since most chemical reactions involve an exchange of atom(s) among the reagents, it is intuitive that such processes should proceed via collisions, or at any rate, close approaches

of the reagents to one another. Since the likelihood of such collisions increases with number density (concentration), the rate is often expressed in terms of the concentrations of the compounds involved (eqn [2]), where *k*, called the rate constant or rate coefficient, represents a concentration-independent factor (which may depend on other parameters, particularly the temperature; see below) and the exponents (*w*–*z*) give the order of reaction with respect to each of the species involved. The overall order of reaction is given by the sum of the exponents.

$$\text{Rate} = k[A]^w[B]^x[C]^y[D]^z \quad [2]$$

The exact form of this expression must be determined experimentally; any of the species present in the reaction system may appear and the exponents, *w*–*z* may or may not bear any relationship to the stoichiometric coefficients *a*–*d*. For example, the low temperature oxidation of methane to carbon dioxide and water, whose balanced equation is given by [II], has a rate expression that may be approximated by eqn [3], where [M] represents the total concentration of all species present, and *k* and *k'* are two different rate constants.

$$\text{Rate} = -\frac{d[\text{CH}_4]}{dt} = k[\text{CH}_4][\text{M}] \left\{ 5 \left(e^{4k'[\text{O}_2]t} - 1 \right) \right\} \quad [3]$$

This rate expression is clearly not intuitively derived from the balanced reaction and indicates that the reaction does not proceed, at a molecular level, by the simultaneous interaction of a methane molecule with two oxygen molecules. A more complex process, involving many individual reaction steps, is responsible for the observed rate expression.

The reaction mechanism is a sequence of elementary chemical reactions, each of which occurs by a single interaction between reagents. This sequence of reactions, taken together, must give rise to the observed rate expression. The rate expressions for elementary reactions are easily written from their balanced chemical equations; for example, the elementary reaction [III], which is the first step in the atmospheric

oxidation of methane, has a rate given by eqn [4], since the reaction takes place by the interaction of *one* OH molecule with *one* methane molecule.

$$\text{Rate} = -\frac{d[\text{CH}_4]}{dt} = k[\text{CH}_4][\text{OH}] \quad \text{[4]}$$

Elementary reactions generally involve atoms, free radicals, or other highly reactive species.

Elementary Chemical Reactions: General Features

If a reaction is known to be elementary, the explicit time dependence of the concentration of all chemical species involved may be obtained through integration of the rate expression. A few instances are of particular interest in atmospheric chemistry.

First-order reactions

These are reactions in which the exponents in the rate expression (eqn [2]) sum to unity. This class of system includes direct photochemical transformations and unimolecular reactions (in the high-pressure limit). For example, the rate expression for photodecomposition of formaldehyde in the near ultraviolet, shown in reaction [IV], is given by eqn [5],

$$\text{Rate} = -\frac{d[\text{H}_2\text{CO}]}{dt} = k(h\nu)[\text{H}_2\text{CO}] \quad \text{[5]}$$

In which the rate constant depends explicitly upon the photon energy, $h\nu$, through the absorption spectrum of formaldehyde. The photolysis rate constant in atmospheric chemistry is denoted as J rather than k , hence the $k(h\nu)$ in eqn [5] for reaction [IV] would typically be written as J_{IV} . This expression is easily integrated to yield eqn [6],

$$[\text{H}_2\text{CO}]_t = [\text{H}_2\text{CO}]_0 e^{-J_{\text{IV}}t} \quad \text{[6]}$$

which represents a simple exponential decay from an initial concentration, $[\text{H}_2\text{CO}]_0$.

Second-order reactions

These include bimolecular reactions between different reagents, as well as self-reactions. The rate expression depends upon the instantaneous concentrations of both species involved in the reaction. For example, the reaction of OH with methane (reaction [III] above) is second order. The time dependence of reactant concentrations is somewhat more complicated than that for first-order reactions, as shown by eqn [7].

$$kt = \frac{1}{[\text{OH}]_0 - [\text{CH}_4]_0} \ln \left\{ \frac{[\text{OH}]_t [\text{CH}_4]_0}{[\text{CH}_4]_t [\text{OH}]_0} \right\} \quad \text{[7]}$$

In laboratory studies of bimolecular reactions, the concentration of one reagent is typically forced to be in great excess, and so remains essentially a constant during the reaction. For example, if $[\text{CH}_4] \gg [\text{OH}]_0$, $[\text{CH}_4]_t \approx [\text{CH}_4]_0$, and the rate of change of the OH concentration can be expressed as in eqn [8].

$$\text{Rate} = -\frac{d[\text{OH}]}{dt} = k[\text{CH}_4]_0[\text{OH}] = k'[\text{OH}] \quad \text{[8]}$$

Here, $k' = k[\text{CH}_4]_0$. In this case, the reaction is said to exhibit pseudofirst-order behavior, and the time dependence of the OH concentration is given by eqn [9].

$$[\text{OH}]_t = [\text{OH}]_0 e^{-k't} \quad \text{[9]}$$

The true bimolecular rate constant is then obtained by performing measurements at many different values of $[\text{CH}_4]_0$, then plotting the observed k' as a function of $[\text{CH}_4]_0$. The slope of such a plot yields k . An example of this is presented below.

Third-order reactions

In the atmosphere, many elementary reactions require the participation of three molecules, and are thus strictly third order. Important reactions such as [V] and [VI] require the participation of a 'third body' (usually designated as M) to remove the excess energy in the newly formed product.

In Earth's atmosphere, M is generally N_2 and O_2 , since these gases account for approximately 99% of the atmospheric composition. The rate expressions of such reactions are properly written as eqn [10], in which the participation of the third body is made explicit.

$$\text{Rate} = \frac{d[\text{HONO}_2]}{dt} = k[\text{OH}][\text{NO}_2][\text{M}] \quad \text{[10]}$$

At the higher pressures present in the lower atmosphere, some (but by no means all!) such reactions are at their high-pressure limits: collisions with M are frequent enough that the reaction exhibits pseudosecond-order kinetics, with the concentration of M incorporated into the observed rate constant.

Sequences of Elementary Reactions

As mentioned earlier, the overall reaction mechanism is constructed from a sequence of elementary reactions, which combine to yield the observed reaction rate expression. Often in such a sequence, a species X is formed as the product of one reaction, and consumed in a subsequent reaction. It can be shown that, if the reaction consuming X occurs more rapidly than its formation, the concentration of X will remain small, and almost time invariant. Here, the formation of X is said to be the 'ratelimiting step' in the reaction sequence, since X is consumed as soon as it is formed. Under these circumstances, the concentration of X is said to be in 'steady state.' Because the majority of atmospheric radicals are highly reactive, the analysis of their steady state concentrations becomes important.

Consider the sequence of reactions given below ([VII]–[X]), which represents a simplified version of the 'oxygen only' chemistry of ozone.

For both of the reactive oxygen species (O and O₃), the rates of change of concentration are given by the difference between the rates of formation (e.g., reaction [VIII] for ozone) and destruction (e.g., reactions [IX] and [X] for ozone).

$$\frac{d[\text{O}_3]}{dt} = k_{\text{VIII}}[\text{O}][\text{O}_2][\text{M}] - k_{\text{IX}}[\text{O}][\text{O}_3] - J_{\text{X}}[\text{O}_3] \quad [11]$$

$$\frac{d[\text{O}]}{dt} = 2J_{\text{VII}}[\text{O}_2] + J_{\text{X}}[\text{O}_3] - k_{\text{VIII}}[\text{O}][\text{O}_2][\text{M}] - k_{\text{IX}}[\text{O}][\text{O}_3] \quad [12]$$

If the concentrations of these reactive species are time invariant, eqns [11] and [12] are set to zero and the rates of formation and destruction are equal. The steady state concentrations of each (designated 'ss') may then be calculated by eqns [13] and [14].

$$[\text{O}_3]_{\text{ss}} = \frac{k_{\text{VIII}}[\text{O}][\text{O}_2][\text{M}]}{k_{\text{IX}}[\text{O}] + J_{\text{X}}} \quad [13]$$

$$[\text{O}]_{\text{ss}} = \frac{2J_{\text{VII}}[\text{O}_2] + J_{\text{X}}[\text{O}_3]}{k_{\text{VIII}}[\text{O}_2][\text{M}] + k_{\text{IX}}[\text{O}_3]} \quad [14]$$

The measured atmospheric concentrations of oxygen atoms and ozone are fairly constant over a time scale of several hours, under constant illumination from the Sun. The analysis given above, although crude, provides a useful picture for how these species' concentrations depend upon altitude (through the total pressure, related to [M]) and the altitude dependence of solar ultraviolet intensities, through k_{VII} and k_{X} .

Temperature Dependence of Elementary Chemical Reactions

The rates of elementary reactions depend upon the reagent concentrations, as discussed above, but also on other parameters, most importantly on temperature, T . The T -dependence of reaction rates is incorporated into k , the rate constant (more properly called the rate coefficient). Empirically, it is often found that over the temperature range important in the lower and middle atmosphere k depends on T exponentially, as shown in eqn [15].

$$k = Ae^{-E_a/RT} \quad [15]$$

In this expression (commonly known as the Arrhenius expression), E_a represents the activation energy, R is the gas constant ($8.314 \text{ J K}^{-1} \text{ mol}^{-1}$), T is the temperature in Kelvin, and A is unimaginatively named the preexponential factor. Careful measurements over wide enough temperature ranges reveal that the preexponential factor depends weakly on temperature, so is strictly written as $A(T)$. The dependence is generally much weaker than exponential, however, and a temperature-independent value for A is often used. This empirical expression may be interpreted simply as follows: for a chemical reaction to occur, the reagents must collide (1) with sufficient energy to overcome any energy barrier(s) along the reaction path and (2) in an appropriate geometry to facilitate product formation. The preexponential factor contains information concerning the collision rate (dependent upon the reagent velocities, and hence temperature) and any geometric constraints on the reaction. The exponential term arises from consideration of the fraction of collisions, under conditions of

thermal equilibrium, which possess energy in excess of some threshold value, E_0 . This energetic threshold is assumed to arise from the presence of energetic 'barriers' along the reaction path, due to the energetic cost(s) of rearranging the chemical bonds. The activation energy is closely related to threshold energy; for our purposes they may be taken as equivalent.

An alternate interpretation considers the elementary reaction to occur in two steps: in the first, the crest of the energetic barrier is achieved; an activated complex (or transition state) is reached. From this point, the reaction may continue to products, or return to reactants as an unsuccessful collision. If the activated complexes are held to be in rapid quasiequilibrium with reagent species, with product formation being rate limiting, a statistical mechanical analysis of a reaction between A and B yields the rate constant in terms of the 'partition functions,' Q , of the reactants (Q_A and Q_B) and of the activated complex (designated $Q^\ddagger$). This can be expressed by eqn [16], where k_B is the Boltzmann constant (equal to the gas constant divided by the Avogadro number) and h is the Planck's constant.

$$k = \frac{k_B T}{h} \frac{Q^\ddagger}{Q_A Q_B} e^{-E_0/k_B T} \quad [16]$$

The partition functions describe how thermal energy is partitioned among the available degrees of freedom in a molecule (i.e., translation, vibration, rotation) and depend only upon molecular properties, such as bond lengths and angles and vibrational energies. These may be determined spectroscopically or calculated theoretically, allowing a priori calculation of the rate constant for the reaction using eqn [16]. However, accurately carrying out these calculations is, in practice, quite difficult and hence is often limited to simple reactions.

This dependence of the rate constant on molecular properties provides an explanation as well for observed isotope effects in reaction rates. Often it is found that reactions of chemically identical, but isotopically different, species will exhibit different rates, with the heavier isotope displaying the smaller rate constant. The smaller vibrational frequencies, and thus lower zero-point energy, of the heavier isotope give rise to somewhat larger reagent partition functions and higher values of E_0 , and hence a smaller rate constant. This is known as the kinetic isotope effect, and is often used to elucidate reaction mechanisms.

Methods for Measuring Atmospheric Rate Parameters

Extracting Useful Parameters from Experiments

A host of methods is in current use for measuring gas phase reaction rates within a laboratory setting. The specific technique employed in any particular case depends somewhat on the particulars of the reaction being studied, and also on the available apparatus in any given laboratory.

As may be inferred from the foregoing discussion, the object of almost all kinetics experiments is to determine the reaction rate coefficient, preferably as a function of temperature, and also, in the case of termolecular and unimolecular reactions, of pressure. Very often this is done by following the concentration of some reactant or product as a function of time, generally

under pseudofirst-order conditions. From eqns [6] and [9], one sees that the apparent rate constant, k' , may be obtained from an appropriate fit to a plot of concentration against time. The values of k' thus obtained are then plotted as a function of the concentration of the reagent held in excess, which is generally varied over about an order of magnitude. The slope of this dependence yields the true second-order rate coefficient at a given temperature.

Figure 1 illustrates this situation for a hypothetical reaction between OH and an unspecified hydrocarbon molecule, RH, at room temperature. The reaction of OH with methane, given as reaction [III] above, is an example of such an OH + RH reaction. Figure 1(a) shows three plots of the decay of OH as a function of time, following its creation at time $t = 0$. The OH concentration is at all times much smaller than that of RH, ensuring that pseudofirst-order conditions are maintained. Curve (i) displays the decay for a low concentration of RH; curves (ii) and (iii) display decays for successively higher RH concentrations. All three exhibit single exponential decays, as required for straightforward pseudofirst-order analysis. Figure 1(b) shows the exponential decay constants obtained from data like those in Figure 1(a), plotted as a function of RH concentration; the slope of this linear fit gives the bimolecular rate coefficient at room temperature. Note the existence of a finite (positive) intercept, indicating a finite rate of

Figure 1 Extraction of a bimolecular rate coefficient from experimental pseudofirst-order reaction conditions, using the OH + RH $\rightarrow$ H₂O + R reaction as an example. (a) Decay of OH as a function of exposure time to RH. Curves (i), (ii), and (iii) display the result for increasing RH concentrations. (b) The pseudofirst-order rate coefficient obtained from fits to data such as that shown in (a), plotted as a function of the (constant) RH concentration. The slope of the linear fit to these data gives the true second-order rate coefficient.

disappearance of OH in the absence of RH. This loss of reagent may be due to a combination of wall reactions, reactions of OH with impurities, and self-reaction of OH.

Modern experiments yield measurement uncertainties of 5–10% on the rate coefficient at any given temperature. Uncertainties are generally larger at lower temperatures, where the reaction rate is smaller for most reactions. The agreement between different laboratories is usually within 10–20% for uncomplicated reactions.

Experimental Techniques

Clearly, the technical issues in measuring reaction rates are: (1) to generate reactive species at some well-defined time $t = 0$; (2) to measure accurately the reagent (or product) concentrations as a function of time, over the course of the reaction; and (3) to minimize losses of reagent due to processes other than the reaction of interest. Implicit in (2) is the absolute identification of the species whose concentration is being followed.

Flow tubes

Two techniques are commonly used to study fairly fast reactions (i.e., those with rate coefficient greater than 10^{-15} – 10^{-16} cm³ mol⁻¹ s⁻¹): flow tube studies and flash photolysis. The flow tube method has several variants, all of which share the same basic principles. A schematic of a typical flow tube apparatus is shown in Figure 2. The flow tube consists of two main components: a temperature regulated outer tube and a concentric inner tube (the moveable injector). One of the reagents, entrained in a fast flow of carrier gas (usually an inert gas such as He or N₂) at low pressure (a few mbar) passes down the flow tube at constant velocity. The second reagent is introduced into the flow via the concentric inner tube, whose longitudinal position may be varied. The zero-of-time is established when the reagents first come into contact with one another; therefore, varying the position of the injector along the tube also varies the amount of exposure of the reagents to one another along the length of the flow tube. Since the reagents move down the flow tube at constant velocity, the contact length, as determined by injector position, is directly proportional to exposure time. The kinetics is studied by monitoring either the disappearance of reagent(s) and/or the appearance of product(s), as a function of injector position (and hence exposure time), in a volume near the end of the flow tube. Optical spectroscopy and mass spectrometry are the two most common methods of detection.

Reactive atomic or radical species are produced continuously by passing a precursor gas through a plasma generated by a microwave or radio frequency discharge (i.e., O and H atoms are formed from O₂ and H₂, respectively). These atomic reagents may be used directly, or they may be converted to different radical species via titration reactions with additional coreactants. Examples of this process are the reactions [XI], [XII], and [XIII] shown here.

Figure 2 Schematic of a flow tube apparatus. Reactants and a carrier gas (M) are introduced from gas reservoirs into the flow tube. One reactant (A) is introduced through the moveable injector (INJ). Atomic or radical reagents are formed by flowing radical precursors (RP) through a microwave discharge cavity (MW). The total pressure in the flow tube is monitored (at P). The concentration of radical reactant (or of product) is monitored by a detector (D) at the exit of the flow tube (shown here as a laser–detector combination).

The radical concentrations are typically between one and three orders of magnitude smaller than those of the molecular reagents, so that a pseudofirst-order kinetic analysis is often possible.

The main drawback of the flow tube technique is that heterogeneous chemistry at the reactor walls may interfere with the kinetics (wall losses). There is also a need for well-defined flow parameters, and axial and radial concentration gradients may exist. However, major advantages of the flow tube technique include excellent reactant and detector versatility. The flow tube technique has been particularly well suited to take advantage of improvements in mass spectrometric detection. For example, developments in chemical ion mass spectrometry (CIMS) allow for the fast detection (~ 1 s) of atmospheric trace gases (e.g., reactive nitrogen species such as HNO_3 and NH_3), with sensitivity in the tens of pptv and lower. Proton-transfer reaction mass spectrometry, a variation of CIMS, has sensitivities nearing pptv for the detection of volatile organic compounds. Another recent development in the flow tube technique is the ability to simultaneously measure the concentrations of two radical reagents (and thus to determine radical–radical reaction rates, via analysis such as that shown in eqn [7]). Conventionally, flow tube reactors operate under low pressures and laminar flow regimes. However, atmospheric pressure flow tubes operating under turbulent flow conditions have recently been developed and characterized, allowing for the study of smaller rate constants as well as termolecular reactions. Finally, the flow tube technique may be adapted to study heterogeneous reactions as well (using, for instance, coated-wall flow tubes or entrained aerosol flow tubes).

Flash photolysis

The flash photolysis method, which also has several variants, was first developed by Norrish and Porter in the late 1940s. In this technique, a suitable radical precursor species is already present in a well-mixed gas mixture, which also contains the second reagent and generally a buffer gas as well. The radical reagent is generated *in situ* by photodissociating the precursor molecule using a short (≤ 1 μs) pulse from a laser or flashlamp (almost always a laser nowadays). For example, methyl radicals are efficiently generated by the photolysis of acetone using

the 10 ns pulse from a 193-nm-wavelength ArF excimer laser (reaction [XIV]).

Similarly, OH may be formed via the 248-nm KrF excimer laser photolysis of nitric acid (reaction [XV]).

The buffer gas (usually an inert gas such as He or N_2) is present to thermalize the photodissociation products prior to reaction. For flash photolysis experiments, the zero-of-time is established by the pulse of light responsible for creating the reactive species. The decay of radical species concentration (or the growth of product species concentration) is monitored as a function of time following that pulse. Measurements are typically made using time-resolved optical spectroscopic methods such as transient absorption or laser-induced fluorescence (LIF) spectroscopy, which require a second laser pulse. In such experiments (often referred to as ‘pump and probe’ experiments), there is a variable delay time between the firing of the radical generating laser (pump) and the firing of the LIF laser (probe), allowing a variable exposure time of the reagents to one another prior to their interrogation. Following each pump–probe cycle, the reaction volume may be replenished with fresh reactants. Unless radical–radical reactions are being studied, the photolysis conditions are maintained such that the concentration of radicals remains much smaller than that of molecular reagents, allowing for a pseudofirst-order kinetic analysis.

Flash photolysis experiments can generally be carried out over a greater pressure range than flow tube experiments, which makes the determination of smaller rate constants possible. The experiments can also be conducted in a larger reactor, which reduces the influence of heterogeneous chemistry at the reactor walls. The main limitation of this technique is the requirement for photolytic generation of the radical reagent; the flash radiation may lead to the production of unwanted photofragments, thereby restricting the choice of reactants. Since flash photolysis experiments are carried out in real-time rather than steady state (as in the flow tube technique), the method of detection must have high time resolution. Advances in laser spectroscopy (narrowing of the laser pulse width and

advent of ultrafast femtosecond lasers) make it possible to study very fast reactions (and sometimes, reaction intermediates) using this method. Other recent developments include the application of time-resolved Fourier transform techniques, especially Fourier transform infrared spectroscopy (FTIR), with increasingly higher time resolution and sensitivity, and the use of cavity ring-down detection in absorption measurement, with the potential to increase detection sensitivity by many orders of magnitude.

Relative rate determination

Often, it is more convenient to measure the relative rate of reaction of two reagents with a third reactant, rather than perform an absolute rate determination. For instance, slower reactions may suffer from significant artifacts such as wall reactions, but their rate constants may be measured with quite reasonable precision (although not necessarily with great accuracy) in this manner. For a simple set of two competing reactions [XVI] and [XVII], it is possible to derive a simple relationship between the concentrations of the reactants and their rate constants, as shown by eqn [17].

$$\ln\left(\frac{X_0}{X_t}\right) = \left(\frac{k_X}{k_Z}\right) \ln\left(\frac{Z_0}{Z_t}\right) \quad [17]$$

Here, X_0 and Z_0 represent the respective concentrations at $t = 0$, X_t and Z_t give the concentrations at time t , and k_X and k_Z represent the two rate coefficients. If one of the rate coefficients is known independently, the other may be determined in this way. Note that the concentration of reactant A need not be measured at all; a similar relationship may be derived for the two product concentrations, meaning that the experimenter may monitor either of the ratios $[X]/[Z]$ or $[P1]/[P2]$, depending on convenience, detection sensitivity, or other experimental factors.

Chamber experiments

Gaining a better understanding of the chemistry behind photochemical smog formation motivated the development of chamber experiments in the 1970s. Large chambers (often referred to as smog, environmental, or simulation chambers) make it possible to study gas-phase kinetics on longer time scales and using lower, atmospherically relevant reagent concentrations (ppm and sub-ppm levels). Chambers may range in size from as small as 25 l to as large as 250 m³. The smaller of these chambers can operate at low pressures while the large environmental chambers usually operate near atmospheric pressure. The main advantage of using large chambers is that they have a very low surface area-to-volume ratio and thus slow homogeneous reactions gain in importance over fast heterogeneous processes which occur on the chamber walls. Early chambers were constructed out of glass or quartz, but nowadays most chambers are made out of (collapsible) flexible Teflon bags. These chambers are usually housed in a temperature regulated, dark enclosure made out of wood or aluminum. For photochemical experiments, this enclosure may be lined with reflective aluminum foil and mounted with lamps. Some chambers are

built outdoors to take advantage of the natural solar spectrum. In most chamber studies, a relative rate method is employed.

In a typical experiment, the first reagent, X (and the tracer gas, Z, for the relative rate analysis), is introduced in a buffer gas (which may be an inert gas, ambient air, or artificial air). The contents are usually allowed to equilibrate over several hours or a few days. The second reagent, A, is then introduced to the chamber to initiate the reaction; radical species are often produced photolytically from A, X, or Z. Application of the relative rate method is ideal as the rate constants thus determined are less sensitive to the presence of impurities and do not depend on knowing the exact concentration of reagent A (which may not be well characterized due to incomplete or uneven mixing). Rates can also be determined in a more complex matrix with multiple reaction partners. Pressure gauges, hygrometers, and thermocouples are usually coupled to the chamber walls, and a variety of analytical instruments can be interfaced to the chamber for the detection of gas-phase species. The large size of the chambers makes them ideal for long-path absorption spectroscopy (particularly FTIR) and in some cases, the instrumentation may even be placed within the reactor. Since the experiments occur on a longer time scale (up to a few days), instruments with lower time-resolution (such as gas chromatography/flame ionization detection) may be used.

A major disadvantage of chamber experiments is their large size and cost. Another disadvantage of using large chambers is that they may be difficult to clean between experiments and so 'sticky' molecules such as HNO₃ may accumulate on the reactor walls. Since reagent concentrations are already very low, the presence of unwanted species may have a significant impact on the chemistry. Environmental chambers have most recently been used to study complex atmospheric processes such as the formation of secondary organic aerosols from gaseous precursors.

Spectroscopic detection methods

Here, we present a brief overview of the various methods in common use at the time of writing. All spectroscopic methods rely upon the resonant absorption or emission of radiation in a wavelength region characteristic of the species being detected. The absorption and emission of radiation by atoms and molecules only occurs in particular spectral regions, corresponding to the energy differences between quantum levels. The amount of radiation absorbed by a sample of molecules or atoms at a particular wavelength, $A(\lambda)$, depends upon the path length of interaction between the light and the sample, l , the concentration of the absorbing species, c , and the molar absorptivity $\epsilon(\lambda)$ of that species. The molar absorptivity is a proportionality constant that describes how efficiently a specific molecule absorbs light of a given wavelength and it is somewhat temperature dependent. As long as the fraction of incident light that is absorbed remains small (i.e., less than about 20% of the incident intensity), then the fraction of light absorbed can be related to the concentration of absorbers by the Beer-Lambert law (eqn [18]).

$$A(\lambda) = \ln\left(\frac{I}{I_0}\right) = \epsilon(\lambda)lc \quad [18]$$

Thus, as long as $\epsilon(\lambda)$ is known, the Beer-Lambert relationship can be exploited to determine the absolute concentrations of reacting species as they change in time during a reaction.

Several implementations are in common use. In direct absorption spectroscopy, $A(\lambda)$ is recorded, either at a specific wavelength or as a function of wavelength, yielding an absorption spectrum. In flow tube methods, this may take place in a sample cell through which the reacting flow passes downstream of the mixing region; in flash photolysis methods, the absorption is measured in the reaction chamber as a function of time after the initial pulse. This variation is commonly known as transient absorption spectroscopy. In its simplest form, a single wavelength, which is chosen to be in resonance with a particular absorption feature, is transmitted through the sample, using resonance lamps or lasers. The time-resolved change in the intensity of this source after it has passed through the sample is measured following the initiation of reaction. Depending upon the exact experimental configuration used, the time resolution can be very good; typically it lies in the range 10^{-6} – 10^{-4} s. This technique is readily coupled to long path-length absorption cells to yield very sensitive concentration measurements. With the recent development of a wide variety of tunable solid state lasers, including tunable diode lasers, quantum cascade lasers, and optical parametric oscillators, coupled with sophisticated long-path absorption cells, such as cavity ring-down systems, it is now possible to measure gas-phase kinetics of a very large number of previously inaccessible species. Under the right conditions, a multiwavelength technique such as FTIR, or broadband cavity-enhanced absorption (IBB-CEAS) may be used to identify many of the reactants and products simultaneously as the reaction proceeds. However, the sensitivity of FTIR is not particularly high, and the wavelength range available in a single IBB-CEAS instrument is limited, so this is not often done, except for instance in environmental chambers, using FTIR.

If a molecule or atom reemits some fraction of the initially absorbed light, fluorescence detection may be used as a sensitive (often zero-background) probe of concentration. This forms the basis for the resonance fluorescence (RF) spectroscopy and laser induced fluorescence (LIF) spectroscopy methods. In RF spectroscopy, the sample is illuminated by an atomic resonance lamp optimized for a particular atom X; resonance emission (i.e., fluorescence) is observed from any atomic X which is present. Reactions of atomic species such as Cl and ground state O have been studied using such lamps. LIF spectroscopy generally utilizes a tunable laser source to scan the excitation wavelength over the absorption spectrum of a molecule of interest. When the excitation wavelength is in resonance with a molecular absorption transition, fluorescence from the excited molecules may be observed. The OH radical is especially well suited to LIF detection, and this is the method of choice in studying its kinetics. LIF spectroscopy is particularly useful in pump–probe flash photolysis experiments. In both RF and LIF spectroscopy, the fraction of absorbed light that is reemitted, depends upon many variables, but remains constant if experimental conditions do not change. The intensity of emitted light (i.e., the fluorescence intensity) is thus a very

sensitive proxy for the amount of absorption, so can be used to track concentrations via a modification of eqn [18].

Some chemical reactions result in the formation of electronically excited products. These excited products may emit light in a process known as chemiluminescence; the emission intensity is related to the concentration of electronically excited products formed in the reaction. Thus, chemiluminescence forms the basis for another detection method based on measuring emission intensity. For example, chemiluminescence is often used to measure NO concentrations. The time dependence of the concentration of NO may be followed by detecting emission (via reaction [XIX]) from electronically excited NO₂, which is formed in the chemiluminescent reaction [XVIII] (here, M represents a bath gas molecule).

Other spectroscopic detection methods, which are no longer in such common use, include laser magnetic resonance and electron spin resonance spectroscopy. Both rely upon the ability of an external magnetic field to perturb the energy levels of an atom or molecule. By varying the magnetic strength, optical transitions may be brought into resonance with a fixed-wavelength light source, allowing light absorption (and hence detection) to occur.

Synopsis

This article discusses the role of methane in the atmosphere and its historic and recent variations. Techniques are described for monitoring its atmospheric abundance from the ground, and recently also from space. An overview is given of the main sources and sinks of atmospheric methane, and the large-scale constraints on the size of these processes as provided by the atmospheric measurements. The use of models is discussed, including the use of inverse modeling techniques for obtaining more detailed information on the spatiotemporal variation of methane emissions and sinks.

Introduction

In 2011, less than 2 parts in 10^6 (on a molar basis) of the Earth's atmosphere was methane (CH_4), but this is a factor of 2.5 more than what was present in 1750, prior to the industrial revolution. Even though this abundance is relatively small, CH_4 is the most abundant organic compound present in the atmosphere, and it significantly affects Earth's climate and atmospheric chemistry.

Methane is a greenhouse gas because it absorbs infrared radiation in a region of the terrestrial IR spectrum that is unaffected by water vapor and carbon dioxide (CO_2), the two most important greenhouse gases. Increasing amounts of atmospheric methane contribute to climate change. Methane currently contributes $\sim 0.5 \text{ W m}^{-2}$ to the total direct radiative forcing (estimated to be 2.84 W m^{-2}) caused by increasing atmospheric burdens of long-lived greenhouse gases since 1750. Only CO_2 contributes more to this total ($\sim 1.82 \text{ W m}^{-2}$).

Methane is removed from the atmosphere predominantly by gas-phase oxidation initiated by hydroxyl radical (OH). Changes in the abundance of atmospheric CH_4 affect the oxidizing capacity of the atmosphere. It is predicted that increasing CH_4 will decrease the concentration of OH in the atmosphere, so it will have an indirect effect on climate by affecting the atmospheric residence times of other reduced, long-lived greenhouse gases that are removed by reaction with OH . Under conditions where the concentrations of compounds called nitrogen oxides ($\text{NO}_x = \text{NO} + \text{NO}_2$) exceed a specific value, oxidation of CH_4 produces O_3 , which is itself an oxidant and greenhouse gas. About 5% of CH_4 emitted to the atmosphere is oxidized in the stratosphere, where it produces H_2O vapor, again potentially affecting climate.

Since CH_4 has the potential to impact climate significantly, it has been targeted by the Kyoto Protocol for reduced emissions. Strategies designed to mitigate the potential impact of CH_4 on climate must rely on a detailed understanding of methane's atmospheric budget (i.e., the balance of sources that emit CH_4 to the atmosphere, and sinks that remove it). Since many of the sources that emit CH_4 to the atmosphere are diffuse and highly variable in space and time, estimating total emissions is difficult. (This is in contrast to anthropogenic compounds such as chlorofluorocarbon compounds, whose emissions are determined from production.) Constraining the global CH_4

budget requires a range of studies including background atmospheric measurements, laboratory and field studies of CH_4 emission rates and the factors affecting these emission rates, and computer modeling studies.

Atmospheric Methane Measurements

Ice Core Measurements

Systematic modern measurements of atmospheric CH_4 abundance began in 1978. Our knowledge of CH_4 abundance prior to that comes from analysis of bubbles trapped in cores drilled and extracted from polar ice. It is assumed that, for methane (and many other stable, long-lived species), air trapped in polar ice bubbles accurately represents the atmosphere at the approximate time when the ice was formed. The longest record of atmospheric CH_4 abundance is for the past 800 000 years, based on an ice core from Antarctica. This record shows that prior to industrialization, atmospheric methane varied from about 350 parts per billion (ppb) during glacial times to 700 ppb during interglacial times. (Note: most methane measurements are reported in a dry-air, mole fraction scale; $\text{ppb} \equiv \text{mol}^{-1}$.) There is excellent correlation between CH_4 abundance and indicators of temperature extracted from the ice. **Figure 1** shows the historic variation of global averaged CH_4 mole fraction estimated from CH_4 measurements in Antarctic ice cores, Antarctic firn, and a globally distributed network of air sampling sites (since 1984). Detailed comparisons of measurements from Arctic ice cores with those from Antarctic cores indicate greater emissions in the northern hemisphere than in the southern. A large increase in methane begins ~ 200 years ago, and it is related to increased CH_4 emissions associated with the increased food and energy demands of a rapidly growing human population.

Ambient Air Measurements

Recent trends and year-to-year variations in global atmospheric CH_4 are monitored using a measurement network, consisting of about 100 sites that regularly receive 'background air'. We define 'background air' as air that is well mixed and representative of a large volume of the atmosphere. These observations generally fall into two categories. The first is measurements

Figure 1 Reconstruction of the globally averaged CH_4 mole fraction in the past 200 000 years determined from ice core, firn, and whole air samples, highlighting variations during: Red, glacial cycles (Dome C Antarctica, courtesy R. Spahni, University of Bern); Green, the industrial revolution (Law Dome Antarctica, courtesy C. MacFarling Meure, CSIRO); Blue, recent decades (South Pole, NOAA–ESRL cooperative air sampling network, available at www.esrl.noaa.gov/gmd).

from discrete samples collected under predetermined meteorological conditions (wind speed and direction) at low frequency (e.g., weekly) in vacuum-tight containers and shipped to a central laboratory for analysis. The second method is measurements *in situ* at a relatively high frequency with an analytical instrument maintained at the sampling site. Gas chromatography with flame ionization detection has been the analytical method most often used for CH_4 measurements, although laser-based optical methods are becoming more common. There are advantages and disadvantages to both sampling strategies. Measurements *in situ* can be costly if multiple measurement sites are desired, and require highly skilled personnel to maintain the analytical instruments and

standard gases. While discrete sampling can achieve extensive geographical coverage at relatively low expense and with greater consistency (since all samples are analyzed on the same analytical system), it cannot match the sampling frequency of measurement *in situ*.

The most cost-effective method for determining large-scale features in the global CH_4 distribution is discrete sampling. Figure 2(a) shows the large-scale variation in methane over the past decades, derived from NOAA's global cooperative air sampling network. Since CH_4 at many sites is variable, particularly in the northern hemisphere, it is useful to smooth the measurements into zonally (i.e., longitudinally) averaged values. To do this, data from the sampling sites are smoothed temporally and as a function of latitude to define a surface of atmospheric methane as a function of latitude and time (Figure 3). The surface is used to calculate zonal averages; examples for the northern and southern hemispheres and global averages are plotted in Figure 2(a). Also plotted in Figure 2(a) are deseasonalized trend curves for each time series. The time derivative of the trend gives the instantaneous growth rate (shown for northern and southern hemispheres only in Figure 2(b)).

Some features in the data are evident. In both hemispheres, methane has been increasing from the start of the measurements in 1984 until 1999. During this period the rate of increase gradually decreased, with large interannual variation, until it came to a halt around the turn of the century. For the first time since the start of industrialization, methane stopped increasing. Between 1999 and 2006 methane levels remained approximately constant, after which the measurements show a renewed increase. The cause of this major growth rate anomaly is not well understood at present. Recent investigations point to changes in natural emissions and sink temporarily compensating for increased anthropogenic emissions.

Superimposed on the trend, the time series in Figure 2(a) show a strong seasonality, with smaller values during summer

Figure 2 (a) Large-scale average time evolution of methane determined from surface measurements, where the cosine of latitude was used to weight for surface area. Plotted are northern hemisphere, global, and southern hemisphere mole fractions, from top to bottom. Deseasonalized trend lines are also plotted for each. (b) Instantaneous CH_4 growth rates determined as the derivatives of the trend lines for the northern (solid line) and southern (dashed line) hemispheres.

Figure 3 Smoothed, zonally averaged representation of the global distribution of methane in the marine boundary layer for the period 2000–11. The grid spacing is 10° latitude by 1 week. Data from 42 sampling sites were used to construct the surface.

than during winter. In the northern hemisphere, the seasonal cycle amplitude, and CH_4 values in general, are larger than in the southern hemisphere, and show a larger variability. This is because there are many CH_4 sources in northern latitudes, and, depending on the trajectory of an air parcel, it can contain highly variable amounts of CH_4 . Methane mole fractions are on average ~ 90 ppb larger in the northern compared with the southern hemisphere, because most of the anthropogenic CH_4 emissions are in the northern hemisphere and atmospheric mixing between hemispheres (or north–south mixing within a hemisphere) is not rapid enough to homogenize CH_4 . Measurements at sites from comparable latitudes indicate that in addition to N–S gradients, longitudinal (or E–W) gradients are also observed despite the short timescales of zonal mixing. For example, CH_4 values at Mace Head, Ireland (53° N in the eastern Atlantic Ocean) are about 10 ppb lower than at Cold Bay, Alaska (55° N) and Shemya Island (53° N) in the Pacific Ocean. Qualitatively, this makes sense because Cold Bay and Shemya are much closer to strong Siberian sources of CH_4 than Mace Head. Another important constraint on the global CH_4 budget is the vertical gradient. Some measure of the vertical gradient is observable in **Figure 4** where CH_4 measurements are plotted for air samples collected above Carr, a site in northern Colorado at 1740 m above sea level (triangles) and Cape Grim, a site on the northwest coast of Tasmania in Australia (circles). At Carr, CH_4 is, on average, greater at the surface, close to sources, than it is aloft. The low values above 6500 m are due to transport from the stratosphere. Above Cape Grim, CH_4 values are greater aloft, since there are only few sources of CH_4 in the high southern hemisphere, and most CH_4 in that part of the atmosphere has been transported from the northern hemisphere in the upper troposphere.

The global averages in **Figure 2** can be used to calculate the ‘burden’ (mass) of CH_4 in the atmosphere (~ 4989 Tg CH_4 in 2011; where 1 Tg = 10^{12} g). When the burden is combined with an estimate of the globally averaged methane atmospheric

lifetime (9.5 year) and a negligible growth rate between 2000 and 2010, total emissions are calculated as:

$$\frac{\partial \text{CH}_4}{\partial t} = Q - \frac{\text{CH}_4}{\tau} \quad [1]$$

where τ is the CH_4 atmospheric lifetime (years), Q emissions (Tg CH_4), and (CH_4) the atmospheric methane burden (also in Tg CH_4). Rearranging eqn [1] and solving for Q , the total source of CH_4 to the atmosphere is ~ 525 Tg CH_4 year $^{-1}$ (including soil oxidation). Some useful constraints on the global methane budget are also obtained from the hemispheric averages. Assuming an interhemispheric, exchange time of 1 year, a methane lifetime of 9.5 years, and steady state conditions, the observed interhemispheric difference of 90 ppb constrains the fraction of emissions in the northern hemisphere to $\sim 70\%$.

Figure 4 Vertical profiles of CH_4 over Cape Grim, Australia, for 15 March 1995 (circles) and Carr, Colorado, on 7 July 1994 (triangles). Cape Grim data courtesy of R. Langenfelds, CSIRO Division of Atmospheric Research, Australia.

Further tests of our understanding of the methane budget are obtained when measurements are compared with models that include atmospheric transport and chemistry. For example, the observed seasonal cycle of CH_4 constrains seasonality of loss, emissions, and transport. Model studies, described in more detail below, have helped to further constrain the methane budget.

Isotope Measurements

Each source of atmospheric CH_4 has a characteristic range of values for the ratios of ^{14}C and ^{13}C relative to ^{12}C , and D (i.e., ^2H or deuterium) relative to H, and the ratios depend on the mechanistic details of CH_4 production and destruction prior to release to the atmosphere. The ratios are measured relative to a standard and expressed in parts-per-thousand deviations from that standard (in units called 'per mil,' abbreviated ‰). Isotopic measurements of CH_4 provide a constraint on its budget; the mass-weighted isotopic composition of CH_4 emissions must equal the value found in the background atmosphere, after accounting for fractionation during loss processes (chemical oxidation and destruction by soil bacteria). For example, the ^{14}C content of CH_4 from biological sources is about 1 part in 10^{12} ^{14}C , while the CH_4 in natural gas has no ^{14}C . (Note: ^{14}C is a radioactive isotope of C that has a half-life of 5730 years, therefore the CH_4 in fossil fuels contains no ^{14}C .) To first order, comparing a measure of ^{14}C in background atmospheric methane with ^{14}C in CH_4 from biological sources will give an indication of the amount of CH_4 emitted during fossil fuel exploitation. Further examples of the use of isotopes are given later.

Remote Sensing

A recent development is to measure CH_4 using open path spectroscopy, which is generally referred to as remote sensing. The instruments are mounted on various platforms, including Earth orbiting satellites. The latter allows space-born greenhouse gas monitoring. A challenge, which so far has still prevented operational application of this technique, is to reach the required measurement accuracy and precision. While there is the potential to sample the entire Earth within several days, in

practice, the actual coverage that is obtained is limited by certain conditions that have to be met to be able to reach sufficient accuracy. For example, instruments that make use of Earth reflected sunlight require cloud free conditions during day time, and a sufficiently large surface albedo. The latter limits the coverage over sea for instruments that measure in the short wave infrared (SWIR), a problem that can partially be overcome by measuring in the direction of sun glint. Despite these limitations, the coverage that is reached by the exploratory mission SCIAMACHY allowed a new view on CH_4 in the atmosphere (Figure 5). Important urban and remote source regions could be mapped that are difficult to monitor from the ground, such as Southeast Asia and Amazonia. In maps of total column CH_4 , regions of elevated methane show up pointing to regional and local sources, associated, for example, with industrial activities and agriculture in China and tropical wetlands in the Amazon rain forest. Atmospheric models can be used to translate these signals into corresponding emissions, as will be explained later in this article.

The more advanced greenhouse gas observing satellite GOSAT allows an important step forward in measurement accuracy using Fourier transform spectroscopy. Compared with grating spectrometers such as SCIAMACHY the spectral resolution is much better. This is achieved at the price, however, of reduced measurement coverage because of the time it takes to record a single spectrum. As with SCIAMACHY, the major challenge is to account for scattering of light on aerosol and cirrus particles along the optical path. In the case of SCIAMACHY, this problem is solved by measuring the ratio of methane to carbon dioxide. The improved spectral resolution of GOSAT allows independent retrieval of methane and carbon dioxide.

Instead of measuring Earth reflected solar radiation, as utilized by SCIAMACHY and GOSAT in the SWIR, other instruments such as Atmospheric InfraRed Sounder (AIRS) and Infrared Atmospheric Sounding Interferometer (IASI) make use of thermal infrared radiation (TIR) emitted by Earth's surface. This approach is less sensitive to clouds and aerosols and allows extension of the measurement coverage to nighttime conditions (including the polar night). Due to the limited transparency of the Earth's atmosphere to infrared radiation, these measurements are most sensitive to methane in the upper troposphere

Figure 5 Vertical column averaged methane mole fractions retrieved from the SCIAMACHY satellite instrument (courtesy C. Frankenberg, JPL). This composite map represents the average of measurements collected in over 2003–10.

and lower stratosphere. By combining the SWIR and TIR measurements, that show very different vertical sensitivities, information is obtained about the vertical gradient of methane, which can in theory be used to separate the influences of surface sources from atmospheric sinks. The challenges are to reach a sufficient accuracy in modeling the vertical transport, and it is not yet possible to calibrate retrievals of CH_4 on the same standard scales used for *in situ* measurements, or at all.

Sources of Atmospheric Methane

Sources of methane at Earth's surface can be classified into ~ 10 major source types. Emission rates may vary by orders of magnitude over a few meters in spatial scale, and they are distributed over enormous geographical regions. The estimation of methane emissions at regional to global scales requires extrapolation from relatively few direct flux measurements, which introduces large uncertainties. Depending on the nature of the processes involved, these extrapolations make use of process-based models (mostly for natural sources such as wetlands and biomass burning) or statistical inventories (mostly for industrial and agricultural emissions). Both methods allow integration of the available information and evaluation against various types of available measurements as discussed in the next section.

In contrast to the diversity of sources, CH_4 is produced by only a few fundamental processes:

1. Microbial production: Decomposition of organic matter by methanogenic microbes under anaerobic conditions in, for example, wetlands, flooded soils, sediments of lakes and oceans, sewage, and digestive tracts of ruminant animals.
2. Thermogenic production: At a few kilometers' depth in soils, pressure and temperature become great enough for the decomposition of organic matter by condensation and cracking processes, eventually resulting in the formation of coal, oil, and natural gas.
3. Pyrogenic production: The incomplete combustion of organic material yields many compounds, including CO, formaldehyde, acetonitrile, and methane.
4. Photolytic production: Various biological carbohydrate polymers, such as cellulose, pectine, and lignin release CH_4 upon exposure to UV radiation. Emissions from living plants are believed to be small as they protect themselves against UV. Larger emissions are expected from plant litter. The significance of this process for the global methane budget is uncertain at present, but the most recent estimates point to a relatively minor importance.

The main source types are discussed in further detail below.

Figure 6 shows the estimated trends of anthropogenic CH_4 emissions per source category since 1970.

Natural Wetlands

Natural wetlands are the largest source of methane to the atmosphere, responsible for about 30% of the global and yearly emissions. These emissions show strong seasonal and interannual variations in response to climatic variations, and explain an important fraction of the observed variation of methane in the atmosphere. A wide variety of ecosystems are classified as wetlands, ranging from Arctic peat bogs to tropical river floodplains. Even temporary water saturated soils, which are generally not classified as wetland, can produce methane. Methane in soil and sediment can escape to the atmosphere by diffusion, ebullition, and plant mediated transport. In the oxic surface layer methanotrophic bacteria consume a part of the methane that is transported from deeper soil layers. Under dry conditions these bacteria extract methane from the ambient air, turning the soil into a net sink of methane. Besides inundated soils, methane production also takes place in sediments of lakes, rivers, and oceans. In such environments, usually the oxic section of the overhead water column acts as an efficient transport barrier, as a result of which only a small fraction of the methane that is produced in the sediment can reach the atmosphere. Emissions from fresh water lakes such as hydroelectric reservoirs and thermokarst thaw lakes are difficult to estimate because of the delicate balance between production and oxidation, which shows strong spatiotemporal variations across and between lakes.

Figure 6 Recent evolution in anthropogenic methane emissions. Data taken from the global emission inventory EDGAR, version 4.1, <http://edgar.jrc.ec.europa.eu>.

Biomass Burning

Biomass burning is a relatively modest source of methane (<10%), but nevertheless important for understanding the observed methane variability because of the high spatiotemporal variability of the emissions. Large amounts of biomass are burned in the tropics in mostly human induced fires related to shifting cultivation, deforestation, burning of agricultural wastes, and the use of biofuels. The fraction of carbon that is released as methane depends on the fuel type and the burning conditions. For example, the efficient burning of dry savannah releases relatively small amounts of CH₄ compared with smoldering forest or peat fires. Since the timing and the extent of tropical biomass burning is closely related to climatic factors (precipitation and temperature), these sources vary strongly with season and contribute to interannual variations in atmospheric methane abundance and its isotopic ratios.

Fossil Fuel Use

The human exploitation of fossil fuel resources leads to important emissions of methane to the atmosphere. At every step along the line of mining, distribution, and use, small amounts of methane are released to the atmosphere. Globally integrated, the contribution of these sources is estimated to be 15–20% of total emissions. Together with agriculture, fossil fuel use is the primary driver of the observed CH₄ increase since preindustrial times. Despite the relatively high level of certainty concerning fuel production and consumption, emissions of methane are still quite uncertain. This is explained by the comparably poor quantification of emission factors and their change over time. In developed parts of the world energy use has become more efficient and clean, motivated in part by economic incentives but also by a growing environmental awareness. For example, the venting of gas from mining shafts is commonly flared to transfer methane into carbon dioxide, which has a lower greenhouse gas warming potential. Overall, emission inventories show declining fossil fuel emissions in Europe and North America, offset by increasing emissions from the growing Asian economies.

Besides human exploitation of fossil fuel, there are also natural emissions of fossil methane from relatively shallow sedimentary basins. Methane escapes to the atmosphere from reservoirs on land and off shore, through volcanic activity (mostly from so called mud volcanoes) and microseepage through faults in tectonically active regions. Large-scale emission estimates are highly uncertain, but might explain a gap between the reported fossil fuel emissions and the global inventory of methane from fossil fuel inferred from radio-carbon measurements.

Agriculture

Agriculture is a major player in the global budget of methane, mostly because of two sectors: animal husbandry and rice production. Methane is produced by methanogenic microbes in the fermentation of feeds in the rumen and lower digestive tract of ruminants. Methanogenesis in ruminants causes a loss of 2–12% of the gross energy of feeds and contributes about 30% of global anthropogenic methane emissions. Ruminant

methane emissions vary with animal productivity, fraction of digestible carbon in the food, and the treatment of animal waste. These in turn vary with farming practices regionally and between countries.

Methane production in rice paddies is in many ways similar to that in natural wetlands, except for the influence of management practices, such as irrigation, fertilization, harvesting, etc. Rice production statistics are a poor indicator of methane emissions. Production continues increasing to satisfy the needs of a growing population, whereas emission estimates show a declining trend. The latter is explained by changes in agricultural practices over time, such as the use of new rice plant varieties, synthetic fertilizers, and intermittent irrigation. Confirmation of the large-scale significance of these trends using atmospheric measurements is complicated by the limited capability to resolve the influences of coexisting sources in densely populated parts of the world.

Waste Handling

Decomposition of organic waste leads to methane production in solid waste dumps, such as landfills, and in waste water streams and reservoirs. The amount of methane that is produced depends on the waste production, the biodegradable organic fraction, landfill storage conditions, and escape pathways. Covered landfills provide a suitable anaerobic environment for methane production, which can escape through leaks in the mantle. It is becoming more common, however, to extract and make use of methane produced in covered landfills, reducing the emissions to the environment. The net influence of increasing waste production and decreasing emission factors varies regionally, complicating its quantification.

Methane sources can be characterized by source-specific isotopic signatures. While methanogenesis results in emissions that are depleted of these isotopes, methane consumption by methanotrophs results in enrichment of these isotopes in the methane left behind. As a result, the net effect depends on the balance between microbial production and oxidation of methane. Methane derived from biomass burning retains the isotopic characteristics of the fuel, which is slightly different for C-3 ($\delta^{13}\text{C} \approx -27\text{‰}$) and C-4 plants ($\delta^{13}\text{C} \approx -12\text{‰}$), but it is highly enriched in ¹³C relative to the isotopic composition of background atmospheric methane ($\delta^{13}\text{C} \approx -47\text{‰}$). As mentioned earlier, fossil sources can be distinguished from other sources by the absence of the radioisotope ¹⁴C.

Atmospheric Sinks

About 90% of atmospheric methane is removed from the atmosphere by reactions initiated by OH. The amount of OH in the atmosphere depends on the concentrations of O₃ and H₂O (vapor) and the UV actinic flux as follows:

Most of the O(¹D) is quenched by reaction with N₂ or O₂ to produce ground-state O(³P), but in the tropics (where up to 3% of air is water vapor) up to 25% reacts as follows:

(Note: the rate coefficient for reaction of $O(^1D)$ with H_2O is 5–10 times faster than the quenching reactions with N_2 and O_2 , so despite the large atmospheric concentrations of N_2 and O_2 , a significant fraction of $O(^1D)$ will result in OH production in the tropics.) The photolysis of O_3 to form $O(^1D)$ depends on sunlight, so OH production varies diurnally. Much of tropospheric O_3 is produced *in situ*. The chemistry that produces O_3 is complex, and the concentration of O_3 is a balance between production and loss. Oxidation of CH_4 is initiated by the following reaction:

Methyl radical (CH_3) adds O_2 to form CH_3O_2 . The subsequent CH_4 oxidation reactions affect O_3 , but the sign of the effect depends on the abundance of oxides of nitrogen (NO_x). In high- NO_x environments (>30 ppt) (ppt = parts per trillion or 10^{12}), O_3 is produced, but with $NO_x < 30$ ppt, O_3 is normally destroyed. The abundance of NO_x also affects OH directly. In NO_x -poor environments OH is destroyed, but with sufficient NO_x present CH_4 oxidation regenerates OH. On average, photochemistry of the troposphere is limited by the amount of NO_x , which means that the oxidation of methane is a net sink of radicals. As a consequence, an increase of methane is expected to decrease OH. Ultimately, most of the CH_4 that reacts with OH produces CO_2 .

Oxidation of CH_4 also influences the isotopic composition of methane. The rate coefficient for reaction of OH with $^{12}CH_4$ is $\sim 0.5\%$ greater than that for reaction with $^{13}CH_4$. This means that CH_4 found in the background atmosphere is enriched in ^{13}C relative to the mass-weighted sum of its sources.

In the stratosphere, reactions with chlorine and electronically excited oxygen atoms, $O(^1D)$, become significant sinks of methane, in addition to OH reaction. In the mesosphere, photolysis also contributes to CH_4 destruction, although this process remains negligible relative to the total sink. Stratospheric methane is relatively enriched in ^{13}C , both because it has been in contact with ^{12}C -depleting OH radicals for a relatively long time and because the Cl reaction leads to a larger fractionation of ^{13}C than the OH radical reaction. Oxidation of methane in the stratosphere is an important source of stratospheric water vapor.

Modeling as a Tool to Constrain the CH_4 Budget

Various types of numerical models have been developed to improve our understanding of the atmospheric methane budget. As discussed earlier, the global burden of methane is relatively well constrained by measurements. Highly simplified models that represent the atmosphere with one or a few boxes (called box models) have been used to interpret observations of atmospheric CH_4 over large spatial scales and long time periods, and to calculate global emissions and sinks. To interpret realistically the measurements on sub-hemispheric scales or at specific air sampling locations, models with finer spatial and temporal resolutions are needed, including detailed parameterizations of atmospheric transport and chemistry.

Box models and three-dimensional (latitude, longitude, and altitude) chemistry transport models typically calculate atmospheric abundances based on a set of hypothetical emissions that are prescribed as boundary conditions to the model. The simulated and observed abundances are then compared to test how realistic these boundary conditions were. It is also possible to compute the emissions and sinks that result in the best possible agreement between model and measurements. This technique, called inverse modeling, is an attempt to reconstruct the emissions and sinks from atmospheric measurements. Here it is assumed that differences between measurements and the ‘forward’ computed abundances can be attributed to emissions and sinks. This requires that inaccuracies in the representation of transport and the errors caused by comparing measurements at a fixed site with model ‘grid-box’ averages (where a grid box may include $200\,000\text{ km}^2$) are small compared with the uncertainties in the sources. Table 1 presents a synthesis of inverse modeling-derived estimates of the global CH_4 budget in the first decade of the twenty-first century including uncertainty ranges (95% confidence limits). As can be seen in the table, anthropogenic sources are estimated to account for 60% of the global emissions, which is a factor of 1.5 larger than total natural emissions and consistent with a 2.5-fold increase of the CH_4 concentration since preindustrial times. The rise in anthropogenic emissions of methane also caused a change in its lifetime because of the feedback of CH_4 on OH. Changes in other precursors of OH such as CO and NO_x also contribute to that change, the net effect of which is not well quantified at present. In addition, emissions from natural sources have changed in response to changes in climate and land use.

Figure 7(a) shows how global emissions varied during 2003–10, comparing the bottom-up and top-down approaches. The inversion-derived fluxes are on average $\sim 10\text{ Tg } CH_4\text{ year}^{-1}$ smaller, and show a temporal variation,

Table 1 Estimates of annual CH_4 emission rates (in Tg CH_4 , where $1\text{ Tg} = 10^{12}\text{ g}$) for the period 2000–10, derived from inverse modeling

Source	Emission rate
Fossil fuels	95 [77–123]
Agriculture & waste	210 [180–240]
Biomass burning	25 [14–45]
Natural wetlands	175 [145–208]
Other natural sources	45 [37–65]
Total	550 [526–569]
Soil oxidation	35 [26–42]
Tropospheric	490 [481–502]
Stratospheric oxidation	20 [12–29]
Total	545 [514–560]

Figure 7 (a) The recent evolution of global methane emissions comparing estimates from the bottom-up and top-down approaches. (b) The large-scale distribution of methane emissions averaged over the period 2003–10, comparing bottom-up and top-down approaches. Top-down estimates are derived from the TM5-4DVAR inverse modeling framework using measurements from 46 sites of the National Oceanic and Atmospheric Administration–Earth System Research Laboratory (NOAA–ESRL) global cooperative air sampling network.

which is in line with the observed increase in global CH₄ since 2007. Large-scale characteristics of the average horizontal distribution of the emissions are presented in [Figure 7\(b\)](#), highlighting the importance of the tropics (30° S–30° N). The atmospheric measurements cause a shift of about 30 Tg CH₄ year⁻¹ from the NH extra-tropics (30–90° N) to the tropics (30° S–30° N).

As illustrated by [Figure 7](#), inverse modeling using background measurements of the global surface monitoring network provides useful constraints on the global methane budget and its variation on interannual timescales and longer. However, the information is generally insufficient to resolve regional sources and sinks since the influence of emissions on atmospheric abundance is quickly attenuated by atmospheric mixing as the distance of the measurements from the sources increases. The solution to regional-scale flux estimation is to make use of high frequency *in situ* measurements from tall towers situated inside the

region of interest. In this case, high-resolution mesoscale models are used that are capable of simulating the large observed variability. Furthermore, a sufficiently dense network of tall towers is required which currently limits the application of this approach to Europe and the USA. An alternative approach to increase flux-resolving power in regions without sophisticated monitoring capabilities on the ground is to make use of satellites. As discussed earlier this approach is still in an exploratory stage because of the challenges to meet the required accuracy and precision. This is true for the measurements as well as for the models. Furthermore, this approach calls for sophisticated optimization methods capable of dealing with large datasets.

Observations for Chemistry (*In Situ*): Ozone Sondes

HGJ Smit, Research Centre Jülich, Jülich, Germany

© 2015 Elsevier Ltd. All rights reserved.

Introduction

Ozone, although a minor constituent, plays a key role in the physics and photochemistry of the atmosphere. As an important absorber of both infrared and ultraviolet (UV) radiations, ozone is of crucial importance for Earth's climate but also as a UV filter for the biosphere. Several methods are available for observation of the vertical distribution of atmospheric ozone. All remote methods, ground-based or space-borne, use optical techniques, while *in situ* methods, (chemical or optical) are made from aircraft, balloon, or rocket platforms. A widely used method for measuring upper-air ozone *in situ* up to altitudes of 30–35 km is through small, lightweight, and compact balloon-borne sondes. The reaction of ozone with potassium iodide in aqueous solution is used to measure the ozone concentration continuously in an electrochemical cell. The sensing device is interfaced to a standard meteorological radiosonde for data transmission to the ground station and can be flown on a small rubber weather balloon (Figure 1).

The electrochemical sondes were developed in the 1960s, primarily to measure ozone in the study of the large-scale dynamics in the stratosphere. Since about 1970, with increased awareness of the photochemical depletion of stratospheric ozone by chlorofluorocarbons and the photochemical

Figure 1 Ozone sounding just after launch at Meteorological Observatory Hohenpeißenberg, Germany. Courtesy of the German Weather Service.

increase of ozone in the troposphere, regular ozone soundings have been made in a global network to observe long-term changes of ozone. Ozone sounding records provide the longest time series of the vertical ozone distribution between the surface and 30–35 km altitude. Up to an altitude of 20 km, ozone sondes constitute the single data source with long-term coverage for the derivation of ozone trends with sufficient vertical resolution, particularly in the altitude region around the tropopause. In addition, ozone sondes are also deployed to study photochemical and dynamical processes in the atmosphere or to validate satellite observations.

Three major types of ozone sondes – Brewer–Mast (BM), electrochemical concentration cell (ECC), and the carbon–iodine (KC96) – are in use since the early 1970s. Each sonde type has its own specific design, and even small differences in instrumental parameters and their uncertainties can have significant effects on the performance of the different sonde types. To assess the performance of the sondes and to quantify any systematic differences between the various sonde types, several intercomparison studies have been carried out since 1970. Most of these studies were based on dedicated short-term intercomparison campaigns in the field and focused on the performance of the sondes in the stratosphere. In addition, comparisons of time series of ozone sonde data with other simultaneously operating ozone profiling devices such as lidar, microwave, or satellites are used to the data quality of long-term ozone sonde records to derive ozone trends.

Instrumental Description

Principle of Operation

The principle of ozone measurement by the electrochemical sonde is based on the titration of ozone in a potassium iodide (KI) sensing solution according to the redox reaction [I]. (An exception is the carbon–iodine ozone sensor, which uses potassium bromide (KBr) instead of KI.) However, the principle of operation is via a reaction mechanism similar to the redox reaction [I].

The titration involves a conductometric method employing electrochemical reaction cells to determine the amount of generated ‘free’ iodine (I_2) per unit time through conversion into an electric current at a depolarizing electrode. Continuous operation is achieved by a small electrically driven gas sampling pump that forces ambient air through the sensing solution of the electrochemical cell. Transported by the stirring action of the air bubbles, the iodine makes contact with a platinum cathode and is reduced back to iodide ions by the uptake of two electrons per molecule of iodine as in reaction [II].

An electric current I_M (μA) generated in the external circuit of the electrochemical cell is directly related, after correction for a background current I_B (μA), to the uptake rate of ozone in the sensing solution. Knowing the gas volume flow rate Φ_P ($\text{cm}^3 \text{s}^{-1}$) of the air sampling pump, its temperature T_P (K) and the conversion efficiency of the ozone sensor η_C , the measured partial pressure of ozone P_{O_3} is determined from eqn [1].

$$P_{\text{O}_3} = \frac{R}{2 \cdot F} \frac{T_P}{(\eta_C \cdot \Phi_P)} \cdot (I_M - I_B) \quad \text{with} \quad \frac{R}{2 \cdot F} = 0.043085 \quad [1]$$

where R is the universal gas constant and F is Faraday's constant. The number 2 originates from the fact that each molecule of iodine (I_2) formed from the reaction of $\text{KI} + \text{O}_3$ will be converted back into 2 iodide (I^-) ions and deliver thereby 2 electrons in the external electrical current circuit to contribute to the measured electrical current I_M . In practice the conversion efficiency η_C is assumed to be unity. In principle, this type of electrochemical ozone sensor is an absolute measuring device. Although the principle of operation is similar for all three sonde types, the instrumental layouts have significant differences.

ECC Ozone Sonde

The ECC ozone sonde was developed by Komhyr in 1969. The ECC ozone sensor is an electrochemical cell consisting of two half-cells, made of Teflon, which serve as cathode and anode chambers, respectively (Figure 2). Both half-cells contain platinum mesh electrodes. They are immersed in KI solutions of differing concentrations. The two chambers are linked together by an ion bridge in order to provide an ion pathway and to prevent mixing of the cathode and anode electrolytes.

ECC sensors do not require an external electrical potential, in contrast to the Brewer–Milford type of electrochemical ozone sensor. The difference in the concentrations of the KI

solutions in the cathode and anode chambers, 0.5–1% KI and saturated KI, respectively, delivers the electromotive force for the ECC.

A small chemically inert gas sampling pump made of Teflon forces ozone in ambient air through the cathode cell, containing the KI-sensing solution of lower concentration, and causes an increase of 'free' iodine (I_2) according to the redox reaction [I]. At the surface of the Pt cathode, I_2 will be converted to I^- through the uptake of two electrons (reaction [II]), while at the anode surface, I^- is converted to I_2 through the release of two electrons. The overall cell reaction is shown in reaction [III].

Thus, one ozone molecule causes two electrons to flow in the external circuit. The electric current is thus directly related to the uptake rate of ozone in the cathode chamber. The ECC ozone sonde is displayed in Figure 2. The instrument, size about $8 \times 8 \times 14 \text{ cm}$, is enclosed in a Styrofoam flight box ($19 \times 19 \times 25 \text{ cm}$). The ECC ozone sonde is nowadays the most widely used sonde type.

BM Ozone Sonde

The oldest ozone sonde type still in routine operation is the BM sonde, which evolved from the Oxford–Kew ozone sonde developed by Brewer and Milford in 1960. The BM-ozone sensor consists of a single electrochemical cell with a silver anode and platinum cathode immersed in an alkaline potassium iodide solution. A polarizing potential of 0.41 V is applied between the electrodes such that no current will flow unless free iodine is present. In operation, ozone in the sampled ambient air is forced through the sensing solution in the electrochemical cell (bubbler) to produce free iodine according to the redox reaction [I]. At the surface of the Pt cathode, I_2 will be converted to I^- through the uptake of two

Figure 2 Schematics of the electrochemical concentration cell (ECC) ozone sonde (a) and sensing cell (b).

electrons (reaction [III]), while at the Ag anode surface two electrons are released through the ionization of two silver atoms to form the insoluble silver iodide (reaction [IV]).

In principle, each ozone molecule entering the sensor causes a current of two electrons to flow through the external circuit.

The most recent version (type 730-10) of the original BM sonde is shown in Figure 3. The reaction chamber (bubbler) is made of clear acrylic glass and contains a cylindrical platinum mesh cathode ($\sim 6 \text{ cm}^2$) and a thin silver wire as anode. The bubbler is filled with 2 cm^3 of neutrally buffered aqueous solution of potassium iodide (0.1%). The electrically driven gas sampling pump is mounted at the right side of the bubbler and forces about $220 \text{ cm}^3 \text{ min}^{-1}$ of ambient air through the bubbler. The sonde is protected by a Styrofoam flight box. Older ozone sounding stations mostly used the BM-sonde type. Most of the stations that are still operational have changed to the ECC ozone sonde type. With an exception of the Meteorological Observatory Hohenpeissenberg (Germany) where BM-ozone sondes are flown since the late 1960s.

A hybrid of a Brewer–Milford type ozone sensor made of acrylic and a nonreactive Teflon pump is manufactured and flown by the Indian Meteorological Department.

Carbon–Iodine Ozone Sonde (KC96)

The KC96 ozone sonde type is a modified version of the KC79- and the earlier KC68-sonde, which was developed by Kobayashi and Toyama in 1966. These sonde types are based on the carbon–iodine ozone sensor type developed in the early 1960s. The ozone sensor is a single electrochemical cell containing a platinum gauze cathode and an activated carbon anode immersed in an aqueous neutral potassium bromide solution. Ozone in ambient air is forced through the sensing

Figure 3 Schematic of the Brewer–Mast (BM) ozone sonde.

Figure 4 Schematic of the carbon–iodine ozone sonde (KC79).

solution, generating ‘free’ bromine molecules (Br_2), similarly to the redox reaction [I]. At the Pt cathode, the bromine is reconverted into bromide (Br^- ions) by the uptake of two electrons, while at the activated carbon anode with the corresponding release of two electrons reaction [V] takes place.

Accordingly, one ozone molecule produces an electric current of two electrons in the external circuit.

A scheme of the sonde is shown in Figure 4. The gas sampling pump and the electrochemical cell are made of methacrylate resin. The pump flow rate is about $400 \text{ cm}^3 \text{ min}^{-1}$, with the pump motor speed being held constant by a governor. The sonde is enclosed in a Styrofoam flight box. The KC sondes were majorly flown by the Japanese Meteorological Agency in their ozone sonde network until 2011. The network deploys now also ECC sondes.

Vertical Ozone Sounding

The set-up of an ozone sounding operation is shown in Figure 5. During normal flight operation, ozone sondes are coupled via special interfacing electronics with standard meteorological radiosondes for data transmission of the measured sensor current and pump temperature plus additional measurement of aerological parameters such as pressure, temperature, and humidity (and, optionally, wind direction and speed). Using the telemetry of the radiosonde, the data measured by the sonde are transmitted to the ground station for further processing.

Figure 5 Set-up of ozone sounding system.

The total weight of the flight package is typically about 1 kg and it can be flown on small weather balloons (Figure 1). Normally data are taken during ascent at a velocity of about 5 m s^{-1} to a balloon burst altitude of 30–35 km. The inherent response time of the ozone sonde is 20–30 s, such that the effective height resolution of the measured vertical ozone profile is 100–150 m.

Figure 6 shows some examples of vertical ozone sounding profiles obtained at a midlatitude site (Jülich, Germany), over the tropical Atlantic (RV *Polarstern*), and at the Antarctic (South Pole). Ozone sondes can be flown under almost all weather conditions, even under heavy cloud or in rainy conditions where optical profiling techniques are rather limited in their capabilities.

Factors Influencing Sonde Performance

Each ozone sounding is made with a new instrument, which therefore has to be characterized properly prior to flight. Consistency of instruments with regard to their quality and characteristics, as well as standardization of operating procedures, is a prerequisite to assure consistent sonde measurements. Several instrumental and procedural parameters (see also eqn [1]) and their uncertainties can have a substantial influence on the quality of the ozone sonde measurements. Changes of these parameters through changes in instrument, operating procedures, or environmental conditions can have a significant impact on the long-term

ozone trends derived from ozone sonde measurements. From intercomparisons between different sounding stations using the same sonde type, it has been shown that the observed differences are for the most part due to the differences in the preparation and correction procedures applied at the different sounding stations. Fortunately, some of the instrumental factors with the potential to influence the observed ozone trends involve postflight data processing, and the data may subsequently be reevaluated when the influences of these instrumental factors and their uncertainties are better understood.

Temperature of Gas Sampling Pump

To correct for changes of the air mass flow rate through the sensor due to temperature changes, the actual pump temperature is measured in-flight either inside the pump or in the instrument enclosure (Styrofoam box). Over the course of a sounding, the pump temperature can decline by typically 10–25 °C. However, in most of the older sounding systems used before the 1990s it was not possible to measure the actual pump temperature owing to the limited number of signals the analog operating radiosondes were able to transmit. Therefore, it was a common practice for either a constant pump temperature or an empirical table of the pump temperature as a function of ambient air pressure to be applied. This procedure can introduce uncertainties of 1–7% in the ozone computations, particularly for the highest altitudes.

Figure 6 Vertical ozone sounding profiles: (a) midlatitude (Jülich, Germany, 51° N 6° E, March 1994); (b) tropical Atlantic (RV *Polarstern*, 6° N 30° W, September 1988); (c) South Pole (preozone hole in July 2001 and ozone hole in September 2001). Courtesy of NOAA/CMDL.

Pump Flow Efficiency

The volumetric flow of the gas sampling pump of each sonde is measured individually before flight. At ambient air pressures below 100 hPa the efficiency of the gas sampling pump degrades, and this is corrected for by applying a correction table of average pump efficiency as a function of ambient pressure specific for each sonde type. Typical correction factors as a function of ambient pressure for each ozone sonde type are listed in Table 1. The correction tables are based on empirical averages obtained from pump flow efficiency measurements made at different air pressures in the laboratory. The uncertainty of the tabulated correction factors increases substantially at pressures below about 20 hPa, which can contribute significantly to the overall uncertainty of the sonde performance above 25–30 km altitude. The uncertainty of the pump flow efficiency is the major contribution to the overall uncertainty of the sonde measurements above 25 km altitude.

Table 1 Pump flow efficiency correction as function of ambient pressure for the three ozone sonde types as obtained from laboratory measurements

Pressure (hPa)	Correction factor		
	BM sonde	ECC sonde	KC79/96 sonde
1000	1	1	1
200	1	1	1
100	1.01	1.01	1.02
50	1.03	1.02	1.04
30	1.07	1.03	1.07
20	1.09	1.04	1.11
10	1.17	1.06	1.25
7	1.24	1.08	1.40
5	1.30	1.10	1.66

Background Current

Prior to launch of the balloon, the background current of each ozone sonde is determined individually, except in the BM sondes for which prior to flight the sonde readings are electronically compensated for the background current. Background signals determined at the surface are typically in the range of 0.1–0.5 mPa ozone partial pressure equivalent. Ozone soundings are thus sensitive to errors in the background signal correction in regions where the ozone concentration is low, i.e., in the upper troposphere. Such errors have the potential to become large if the background signal is similar in magnitude to the ozone signal. This is particularly the case in the tropics (Figure 6(b)), but also in the Polar Regions when the stratospheric ozone hole occurs (Figure 6(c)). For the conventional method of background correction it is assumed that the background current is proportional to the oxygen partial pressure, so that this offset gradually declines with decreasing pressure and is vanishingly small in the upper troposphere and stratosphere. However, laboratory studies do not show any oxygen dependence of the background current and it is more appropriate to use a constant background current correction throughout the entire sounding profile. The origin of the background signal is not really understood. The timed background measurement during the preflight preparation is directly correlated to the ozone exposure of the sensing cell. Therefore, the background current is most likely not a time invariant property of the electrochemical cell but the result of a minor but still slowly decaying contribution to the measured cell current caused by an additional minor and slow reaction pathway of the chemical oxidation of ozone in the cathode sensing solution. However, more research is needed to resolve the problem of ECC-sensor response with the fast and slow signal component.

Conversion Efficiency

The conversion efficiency includes both the efficiency of absorption of O_3 into the sensing solution and the stoichiometry of the conversion of O_3 into I_2 . During normal operation both parameters are unity, so that the conversion efficiency is also assumed to be unity. However, in the course of a sounding, the uncertainties of the sensor cell characteristics can increase. For example, a certain percentage of the sensing solution evaporates at a rate dependent on the temperature of the cell and the ambient pressure encountered during the sounding. For the ECC sondes, this means that the concentration of the sensing solution increases, which can enhance the sensitivity of the ECC sensor and can increase the uncertainty of the ozone measurement.

For ECC sondes, this increase of sensitivity is significant in presence of the 'pH-buffering' phosphate chemicals. Usually, the sodium-hydrogen phosphate buffer is added to the cathode sensing KI solution to keep the pH neutral at 7.0. However, the buffer can also be the cause for the controversy of yielding a stoichiometric factor (I_2/O_3) larger than unity. The reaction mechanism and stoichiometric factor of the net iodimetric reaction [I] has been studied by many investigators using a variety of KI solutions and pH-buffers. It appears that depending on the concentrations of KI and the pH-buffer, the stoichiometric factor can expand up to 1.25. For BM or KC sondes, this effect is negligible because these sondes operate at much lower concentrations of sensing solution.

When ECC sondes of the same type are operated with the different cathode sensing solution strength that are nowadays applied, it has been shown that significant differences (~ 5 – 10%) in the ozone readings can occur. In addition, the performance characteristics of ECC sondes from different manufacturers can be significantly different ($\sim 5\%$), even when operated under the same conditions.

Another source of uncertainty is the influence of local air pollution, which can have detrimental effect on the conversion efficiency, i.e., on sensor performance. Ozone measurements by a KI method, as in the electrochemical ozone sensor, are sensitive to interferences by oxidizing or reducing agents. However, several laboratory experiments have shown that for moderate polluted air, sulfur dioxide (SO_2) is normally the only trace gas that can produce significant negative interferences in the measurements of ozone. As a reducing agent, SO_2 converts the iodide produced from the ozone-iodine reaction back to iodine. A memory effect can occur if excess of SO_2 is accumulated in the sensing solution of the sensor, which can affect measurements not only in the polluted boundary layer itself but also up to 1–2 km above.

Total Ozone Normalization

Optionally, ozone sonde profiles are normalized so that the integrated ozone column obtained from the sonde profile plus an estimated residual ozone column above the burst altitude is adjusted to an independent nearby total ozone column measurement by, e.g., a Dobson or Brewer spectrophotometer. Standard procedure for calculating the residual ozone column is to assume a residual column with constant mixing ratio

equal to the measured value at the top of the sonde profile. Uncertainties in the sonde readings of pressure and ozone at the burst altitude, and also the assumption of constant mixing ratio, can introduce significant uncertainties in the estimation of the residual ozone column. This can be improved by an alternative method in which a climatology of residual ozone column data obtained from satellite observations is used. However, the influence of uncertainties in pressure readings at the bursting point remains.

The use of normalization to correct the profile conflicts with the fact that the electrochemical ozone sonde is, in principle, an absolute measuring device. However, even if the total ozone normalization factor is not used to correct the sonde profile, it provides a screening test for unreliable soundings using the criterion that the normalization factor may not deviate more than about 10–20% from unity. However, a normalization factor of unity is not a guarantee that the profile is correct. In routine operation, the normalization factors for ECC sondes are in the range of 0.9–1.1, while BM and KC sondes show normalization factors of 0.8–1.2.

Radiosonde Pressure and Temperature

Errors in radiosonde pressure or temperature measurements will imply corresponding errors in calculated geopotential heights, causing measured ozone concentrations to be assigned to incorrect altitudes and pressures. This is potentially an important issue for the derivation of trends, as radiosonde changes may therefore introduce vertical shifts in the ozone profile, and apparent changes in ozone concentration at a given height. A number of different radiosonde designs, from several manufacturers, have been used in the global observing network over the last four decades. At pressures below 50 hPa, significant bias effects of 5–10% in the ozone profile can occur, particularly for the radiosonde types used before 2000. Through the use of the Global Positioning System, modern radiosondes can measure geopotential heights with a higher accuracy. This will reduce any bias effects in the measured pressure, i.e., ozone profile significantly.

Precision and Accuracy

To quantify the precision and accuracy of the three different types of ozone sondes, several comparison studies of sondes with other ozone profiling techniques have been made since 1970. Most of the intercomparisons have been conducted in the field to assess the sonde performance up to 30–35 km altitude. However, short-term intercomparisons are more or less 'snapshots' and may not necessarily reflect the performance of ozone sondes under operational field conditions. Comparison studies of time series of ozone sonde data with other simultaneously operating ozone monitoring methods such as lidar or microwave are more suitable for assessing the data quality of the ozone sonde measurements in regular operation. In addition, intercomparisons conducted in a controlled environmental chamber capable of simulating real sounding conditions, where a UV photometer serves as reference, allow specific questions arising from field intercomparisons to be addressed.

Owing to the much lower concentrations of ozone in the troposphere compared to the stratosphere, the performance of the sondes and the typical instrumental and operational factors determining precision and accuracy are rather different in these two regions of the atmosphere. However, most intercomparison studies, particularly before 1990, focused exclusively on the sonde performance in the stratosphere and only a few intercomparison studies have addressed the sonde performance under typical tropospheric conditions.

Stratospheric Performance

In general, all intercomparison studies, short-term as well as long-term, have indicated that in the lower to middle stratosphere between the tropopause and ~ 28 km, the three different sonde types show consistent results provided the individual measured sonde profiles have been normalized to ground-based total ozone column measurements at the launch site. This can be understood from the fact that the normalization is mainly weighted to the ozone in the lower stratosphere, which contains most of the column ozone. In this altitude range, the precision of the various sonde types is within $\pm 3\%$, while any systematic biases compared to other ozone-sensing techniques are smaller than $\pm 5\%$.

For altitudes above 28 km, the results are not so conclusive and the measurement behavior of the different sondes is different and cannot be generally characterized. The BM sonde used by the established (long-term record) stations (e.g., Hohenpeissenberg) show systematic underestimations of ozone that increase with altitude (-15% at 35 km). For the ECC sondes, there is some evidence suggesting that measurements agree with each other and with reference techniques to within $\pm 5\%$. The Japanese KC68/79/96 tends to overestimate ozone above 30 km. The data quality of sondes above 28 km is strongly influenced by the performance of the air sampling pump and its efficiency decreases at lower pressures. However, most of the intercomparison studies show that the performance of the ECC sondes between 28 and 35 km is still rather good and even tends to overestimate the ozone concentration compared to lidar measurements. There are some experimental indications that for ECC sondes there is probably a compensating effect due to evaporation of the KI-sensing solution, which will cause an increase in concentration and may result in a higher sensitivity of the ozone sensor. However, in general the sonde data above about 28 km are less reliable and should be used with caution, at least for the non-ECC types.

Tropospheric Performance

There is a dearth of sonde validation studies for the troposphere and, because of the small number of comparisons, only estimates of the reliability of the sonde data records below the tropopause can be made. Further, because ozone values are much lower in the troposphere than in the stratosphere, the impact of instrumental errors and variability is larger. Intercomparison campaigns between 1970 and 1990 have shown systematic differences between sonde types, typically varying from 10 to 15%. Campaigns conducted after 1990 have shown that the BM and KC79/96 sondes are less precise than the ECC types and that the ECC sondes deliver much more consistent

results than the other two types of sondes. The precision of the ECC sonde is better than $\pm(5$ to $10)\%$ and shows a small positive bias of about 3%. The BM and KC79/96 sonde showed precisions in the range of $\pm(10$ to $20)\%$, but there are no indications of any bias larger than $\pm 5\%$. Key issues of uncertainty are the background correction and the use of the total ozone normalization factor.

Changes of Instruments or Operating Procedures

Apart from a few exceptions, nowadays, ECC ozone sondes are predominantly flown within the global ozone-sounding network or deployed in scientific field experiments. Laboratory and field experiments have demonstrated that small changes of the ECC-sonde instrument or operating procedures can significantly influence its performance. For example, the performance characteristics of two different ECC-sonde types, manufactured by either Science Pump Corporation (Model type: SPC-6A) or Environmental Science Corporation (Model type ENSCI-Z), can be significantly different, even when operated under the same conditions. Different ozone readings were obtained when sondes of the same type are operated with different cathode sensing solutions. This means that for ozone sounding stations performing long-term measurements, a change of the sensing solution type or ECC-sonde type can easily introduce a sudden step of $\pm 5\%$ or more in their records, affecting the determination of ozone trends. Existing artifacts in long-term sounding records caused by changes of the instrument or operating procedures can be resolved by homogenization either in space (between different stations) or in time (long-term changes). This can be achieved through use of generic transfer functions, which can be derived from intercomparison experiments or dual balloon soundings.

Synopsis

The principles behind the large suite of instruments available for *in situ* particle observations are described. Instruments use condensation, optical scattering, electrical mobility, direct capture, absorption, and dissociation to provide highly resolved space and time measurements of aerosol number, size, mass, composition, optical properties, shape, and nucleating characteristics, when a full suite of instruments is available. Such measurements are required to fully characterize and understand the role of particles in certain aspects of heterogeneous chemistry, radiative transfer, cloud formation, and precipitation.

Introduction

History

The scientific observation, and discovery, of particles or liquids suspended in air, or aerosol, began with Tyndall in the 1850s through his observation of forward scattering from particles in direct sunlight. This led to Tyndall's further investigation of smaller particles by dark field microscopy, establishing the basis for nephelometers, ultra microscopes, and optical particle counters. At nearly the same time the work of Epsy, Coulter, and Aitken led to the realization that particles were required for the condensation of water in air and that this could be used to measure concentration, leading to condensation particle counters. Human interest in aerosol significantly preceded these discoveries, due to the obvious impact of aerosol on life through air pollution: the foul air of Rome, coal burning in London, mortality of hard rock miners. Thus, the first concerted measurements of aerosol, in the early 1900s, were focused on high concentrations of respirable particles which, when captured in alveoli, will lead to various forms of emphysema, depending on the contaminant particles: silicosis, tabacosis, and asbestosis. The natural role of particles in the formation of droplets and ice crystals in clouds, and their possible use in cloud seeding, was apparent by the end of the 1940s. The pivotal role of aqueous particles in mediating the atmospheric concentrations of reactive trace gases, in particular stratospheric ozone, became apparent in the 1980s. The interaction of particles with radiation was described well by the early 1900s; however, the impact of aerosol on the Earth's radiation balance has only recently been of significant interest as we strive to understand, and forecast, the impact of the increasing atmospheric abundance of carbon dioxide on the Earth's future. As the twenty-first century begins, the measurement of aerosol particles appears even more important than at the beginning of the twentieth century, when measurements began.

Aerosol Characteristics

The instruments and tools available today to measure aerosol are impressive: filters, electron microscopy, condensation particle counters, optical particle counters, nephelometers, mobility analyzers, impactors, mass spectrometers, lasers, fast microprocessors, and ample storage facilities. The task, however, is more impressive and no instrument can provide all the information desired. Atmospheric aerosols arise from the Earth's surface,

through combustion, mechanical disturbance, and gas to particle conversions from gaseous organic and volcanic emissions. Particle sizes range from <1 nm to >10 μm , concentrations from $>10^4$ cm^{-3} for small particles to $<10^{-3}$ cm^{-3} for large particles, and mass concentrations from <1 $\mu\text{g m}^{-3}$ to >1 mg m^{-3} . Particle shape varies and particles may be externally or internally mixed (Figure 1). Tropospheric particles contain a large fraction of the nonnoble elements in the upper half of the periodic table (Figure 2). The most common volatiles are water, organics, nitrates, sulfates, and ammonium. The most common crustal materials are aluminum, silica, and iron oxides. Aerosol particles provide cloud condensation and ice nuclei. Removal occurs through sedimentation and cloud processes. Residence times are typically <30 days in the troposphere, less than atmospheric mixing times, leading to large spatial and temporal structure. Stratospheric aerosols are well mixed, within a few years of penetrating volcanic eruptions, with residence times of years.

To completely characterize atmospheric aerosol would require time and space-resolved measurements of aerosol number, size, mass, composition, optical properties, shape, charge, and nucleating characteristics. No instrument is capable of this; however, individual *in situ* instruments and techniques are available which can measure each of these properties relying on condensation, optical scattering, electrical mobility, direct capture, and dissociation. *In situ* implies measurements at or in the immediate vicinity of an instrument. *In situ* aerosol measurements provide highly resolved space and time measurements, while suffering from severely limited space and time coverage, which are more easily obtained from remote aerosol measurements, such as lidar, limb extinction, or other electromagnetic-radiation-based sensors. *In situ* measurements, however, offer the only way to describe some of the specifics of aerosol populations required to fully characterize/understand heterogeneous chemistry, radiative transfer, cloud formation, and precipitation. *In situ* measurements play vital roles in improving our understanding of each of these fundamental areas.

Uncertainties

In situ instruments measure either an ensemble of particles or single particles, and are either extractive or noninvasive. Extractive instruments pull aerosol samples into a sampling chamber, while noninvasive instruments define a sampling volume external to the instrument, generally optically. Ensemble instruments are sensitive to the entire size distribution at once and thus measure directly integrals of the size distribution: mass, surface area, composition, absorption, scattering, or extinction. Single particle measurements provide size distributions of most of these quantities, and nucleating characteristics. Extractive instruments provide a larger suite of properties and are required for particles $<0.5\text{--}1.0\ \mu\text{m}$. All extractive instruments suffer from biases due to the inlets and tubing

leading to the sampling chamber. An ideal inlet has an internal air speed matching the speed of air flowing past the inlet, is straight, not too long, and does not heat the sample. As real inlets deviate from the ideal they may over- or under- count the edges of the size range; may lose particles in the inlet tube due to turbulent, inertial, electrostatic, or diffusional impaction; and particle size may change due to evaporation. Noninvasive instruments are required for particles $>10\ \mu\text{m}$, and are generally used for cloud particles. The illuminated volume defines the sample volume. Uncertainties arise from particles at the sample volume edge and from fragments of particles broken on the shrouds for the optical source and detector. Aside from uncertainties introduced by the inlet, or sample volume, all instruments have additional sampling biases related to sensitivity to specific size ranges, number concentrations, mass concentrations, and ionization thresholds. Each specific instrument has its own calibration and sampling efficiency challenges, and not all can be fully met, leading to instrumental limitations for many applications; see approximate size limitations in Figure 3. Adequate descriptions of these challenges and limitations cannot be accomplished here and will not be attempted. Instead the general principles underlying the instruments used to measure the wide array of aerosol properties will be focused on. The article will be organized around these aerosol properties. Table 1 summarizes the instruments and properties measured.

Although some aerosol sampling techniques, such as microscopy, spectroscopy, and gravimetry, provide primary data and are thus self-calibrating, most aerosol instruments require calibration against primary standards. Once instrument response functions are established partial calibrations are usually adequate for routine operation. The most fundamental primary standard is electron microscopy, for nonvolatile particles. Commercial primary standards include polystyrene latex beads of specific single sizes and aerosol generation and classification systems capable of supplying reliable monodisperse aerosol samples between 0.01 and $1.0\ \mu\text{m}$ for several aerosol compositions. Sample flow rates must also be carefully measured. However, even with careful calibration, the precision of most aerosol measurements is 20% or more, significantly higher than most gas phase measurements. The reason for this has less to do with the maturity of the instrumentation, than the complexity of aerosol particles compared to gas molecules. For gases, molecular composition, structure, size, shape, and mass are mostly well known. The primary measurement is concentration, and, at levels of parts per trillion, the number concentration of molecules exceeds total aerosol populations by factors of a thousand or more. Thus counting uncertainties are small. For aerosol particles counting uncertainties are large and are dominant for the largest particles, none of the properties listed above are known a priori, and often the particles are not well mixed so particle shape and composition will vary among the particles sampled, Figures 1 and 2, in addition to the normal variations in size and mass.

Chemical Properties

Composition

Aerosol mass spectrometers provide the biggest advances in the past 20 years for aerosol composition measurements. These

Figure 3 Size range for *in situ* aerosol measurement techniques as a function of diameter (μm). Interdecadal divisions on the log scales are at approximately 2 and 5. The size range for the nucleation, accumulation, and coarse modes typically assumed for atmospheric aerosol are shown at the top. Particle equivalent mass for a density of 1 g cm^{-3} is shown at the bottom.

single particle extractive instruments size and chemically analyze individual aerosol particles in real time, and several commercial instruments are available. Prior to this capability nearly all the chemical information was based on postanalysis of captured particles. Mass spectrometers consist of an evacuated inlet, which focuses particles into a central beam, a size determination, particle volatilization and ionization, and a mass to charge (m/z) detector, [Figure 4](#). The differences in these pieces define the different aerosol mass spectrometers available. Inlets may consist of single orifices, capillaries, or aerodynamic lenses, with the latter two capable of focusing a range of particle sizes. An aerodynamic lens is a series of

decreasing orifices, with each orifice concentrating successively smaller particles onto the central beam and is most common. Sizing is accomplished through either optical scattering or time of flight from the inlet exit to the target. Volatilization is accomplished by heating or laser ablation. Heating vaporizes only the volatile components, whereas laser ablation also provides refractory components. The vaporized molecules are ionized by electron impact, photoionization, or chemical ionization. The efficiency of ionization determines the quantitative nature of the measurement. Electron impact and chemical ionization are more well characterized, leading to more quantitative mass fractions when used. In contrast

photoionization leads to less quantitative results. The ion detectors are primarily either quadrupole or time of flight. Quadrupole detectors focus ions of specific m/z ratios onto the electron detector. Only one m/z ratio can be sampled per particle due to timing limitations. Scanning through the m/z ratios for a series of particle impacts provides a quantitative mass spectra. Time of flight spectrometers use an electric potential to accelerate ions into a drift tube ending at the electron detector. The spectrum of arrival times provides the

mass spectrum since the drift velocity is mass dependent. The drift tube may be straight or bent to increase the length and thus resolution.

Prior to the advances in aerosol mass spectrometry chemical information was primarily limited to chemical analysis of particles captured on filters and more recently in high purity water. These ensemble invasive techniques can determine the elemental, ionic, and carbonaceous composition of aerosol, and are the only possibility for some applications. Elemental

analysis is accomplished by colorimetry, X-ray fluorescence, γ -ray emission, or atomic emission or absorption spectroscopy. Elemental concentrations are identified by spectroscopy of absorption or emission lines. Colorimetry uses wet chemistry to produce a solution whose light absorption is quantified. X-ray fluorescence and γ -ray emission use an energy dispersive detector to measure characteristic X-rays or γ -rays emitted from excited states of the elements. X-ray fluorescence is induced by exposure to X-rays or protons, γ -ray emission by exposure to neutrons. For emission and absorption spectroscopy, samples are dissolved and vaporized. Atoms excited by arcs, inductively coupled plasmas, sparks, or lasers will emit. Alternatively absorption of radiation by samples dissociated into ground state atoms in a flame can be measured.

Ions such as, SO_4^{2-} , NO_3^- , and NH_4^+ , major components of ambient aerosol, can be measured by colorimetry, ion chromatography, selective ion electrodes, infrared or Raman spectroscopy, or mass spectrometry. The first three techniques measure only the aqueous fraction of the aerosol. Ion chromatography, most widely used, separates sample ions within a column using ion exchange. Ion concentrations are measured with conductivity. Particle into liquid samplers inject the aerosol into a region of high water supersaturation forcing water to condense on the aerosol. The water droplets containing the aerosol are collected and inorganic ion fractions determined with ion chromatography. To remove gaseous contaminants the aerosol stream is usually preceded with a denuder.

Infrared or Raman spectroscopy uses infrared photons at energies characteristic of molecular vibrational bands, which are absorbed in proportion to molecular concentration. Visible photons, which inelastically (Raman) scatter from samples display frequency shifts characteristic of molecular vibrational bands. These techniques are also sensitive to organics and oxidized organics. For mass spectrometry, a laser volatilizes and ionizes the collected samples, or an ion beam removes, 'sputters,' ions off particle surfaces. Ion detection then proceeds as described above.

Carbon Content

Measurement of carbon in aerosol is another area with recent significant advancement, while remaining particularly challenging, due to the thousands of organic species, plus black carbon, which appear in particles. Mass spectrometers provide measurements of the volatile organics, but laser ablation is required for black carbon. Specific black carbon instruments are invasive and range from ensemble filter, cavity ring down, and photoacoustic, to single particle absorption. Total carbon can be determined by oxidizing filter samples and measuring the CO_2 . Techniques to separate total carbon into elemental and organic are attempted; however, there is no accepted standard. Techniques include slowly volatilizing organics or graduated chemical extraction. All other techniques rely on the absorption of light by carbon. Continuous measurements of light absorption by aerosol collected on filters provide good relative values but have large uncertainties. Cavity ring-down spectrometers trap photons in a sample chamber with highly reflective mirrors. Light intensity decays as the light is absorbed and scattered by the ensemble of particles in the cavity. The decay time then measures aerosol extinction of the light. To

obtain absorption requires an independent measure of scattering. Photoacoustic spectrometers measure absorption directly by measuring the acoustic waves resulting from heating of aerosol in the sample cavity by the absorption of light. The laser source is modulated at a characteristic frequency of the sample cavity, thus amplifying the sound for detection. The single particle soot photometer measures the incandescent black body radiation from particles, which are vaporized within the cavity of an infrared laser. Only absorbing particles will absorb the laser energy and become heated, with the time to vaporization, and the temperature, dependent on the carbon content. Particle size is measured simultaneously by scattering. This technique can be combined with mass spectrometric measurements of the incandesced particles for more detail.

Index of Refraction

Index of refraction is a function of aerosol composition, and if particle molar ratios are known, index of refraction can be derived. Another approach is to use size distribution measurements to calculate scattering for comparison with scattering measurements. The index of refraction is used to match the calculated and observed scattering. There have been a few attempts to measure particle index of refraction directly using optical instruments with detectors at several angles. Changes in index of refraction will lead to dissimilar changes in angular scattering, which should be sensible. These multiangle approaches have not proven to be very robust.

Physical Properties

Concentration

The first measurements of number concentration, the tyndallometer, and ultramicroscope were limited to particles large enough to scatter visible light, approximately $>0.3\ \mu\text{m}$, which misses the majority of aerosol. These instruments, however, were quickly followed by Aitken's condensation nuclei (CN) counter, variations of which remain the standard technique for number concentration. All CN counters consist of a saturator, condenser, and detector. The working fluid, water, butanol, and ethylene glycol, is evaporated into the aerosol stream in the saturator. Supersaturation occurs in the condenser and is achieved with either expansive or conductive cooling. Expansive cooling and water were originally used to create a cloud, which attenuates a light beam; however, none of these original instruments remain in service. Today, continuous flow instruments with conductive cooling supersaturation chambers are used. Typically air is saturated with *n*-butyl alcohol, at temperatures near $30\ ^\circ\text{C}$, before entering the condenser, held near $0\ ^\circ\text{C}$, where the air becomes rapidly supersaturated. Each particle acts as a condensation site and becomes a droplet large enough to be detected optically. The extent of supersaturation, controlled by the temperature difference between saturator and condenser, determines the minimum particle size, which will be condensed upon and thus be counted. Size distributions can be measured by preselecting particles with a diffusion battery or differential mobility analyzer, or by carefully controlling the supersaturation to activate successively smaller particles. An alternate total concentration measurement can be accomplished by charging

the aerosols with unipolar ions and then measuring the current as the aerosols are collected on a filter in a Faraday cage, assuming each particle carries one electron.

Size Distribution

There are a number of mature instruments to measure size distribution; however, only microscopy provides the physical or geometric size, but is quite laborious. The other methods provide either the optical or aerodynamic size. Optical size is provided by optical particle counters, among the first instruments to provide size distribution, which consist of a light source, dark field scattering chamber, and photodetector. Visible wavelengths were initially used, thus optical particle counters. Particle size is determined from the intensity of scattered radiation using Mie theory. To limit the influence of Mie resonances for particles near the wavelength of light, instruments use either a white light source or a large solid angle for detection of scattered light. Both approaches smooth the counter response function and limit the sensitivity to particle index of refraction. Sensitivity is determined by particle size for small particles and by particle concentration for large particles. Scattered radiation from small particles approaches Rayleigh scattering from molecules and therefore the detection limit. Particles greater than a few micrometers are rare, thus concentration uncertainties are large; however, the signal from one particle is well above instrumental noise. An alternate ensemble approach illuminates a sample with a laser and measures the scattering pattern, which has variations dependent upon average particle size and size distribution. The fluctuations arise from constructive and destructive interference of the scattering from individual particles as they move due to Brownian motion. This technique, known as photo correlation spectroscopy, measures the mean diffusion coefficient of the particles, and hence their mean size and a rough size distribution. The technique is sensitive to nanometer sizes. To achieve sufficient aerosol concentrations, samples are often captured in a liquid, producing a colloidal suspension. If particle concentrations are high enough, such as in flames or smokes, the technique can be used directly on aerosol samples as opposed to hydrosol samples.

Aerodynamic size is measured in several ways. Differential mobility analyzers or electrostatic aerosol spectrometers consist of an aerosol charging region, a drift tube with an applied electric field, and an outlet to a particle sensor. Charging regions usually contain sources of low energy electrons or alpha particles and produce bipolar equilibrium charge distributions which are a function of size. The particles then pass to a large diameter annular opening at the beginning of the drift tube. Particles with the appropriate charge polarity are attracted across a region of filtered air to a central rod held at a specific voltage. The particle drift velocity is inversely proportional to aerodynamic size. Only particles with the appropriate charge and aerodynamic drag to arrive at a small open annulus near the central rod will exit, providing a population of uniformly sized particles. The aerosol detector is usually a CN counter, but could be a filter and Faraday cage. Scanning the center rod across a range of voltages provides a differential size distribution if the size-dependent charge distribution is known, which also accounts for multiply charged particles. If the exit annulus is replaced by a large opening, all charged particles too large for collection on the central rod will

exit, providing a cumulative size distribution measurement. This approach was used by instruments called electrostatic aerosol analyzers. Final size distributions are available after an inversion. The lower size limit is constrained by inefficient charging for small particles, and the upper limit by the length of the drift tube. For supermicrometer particles, size can be measured with the aerodynamic particle sizer, which injects particles from a sample nozzle into a fast airstream. Particles are accelerated toward the airstream velocity based on their inertia and aerodynamic drag. Particles not fully accelerated prior to a velocity measurement with dual laser beams can be differentiated, based on their resistance to the airstream, which depends on both inertia and aerodynamic drag. Fully accelerated particles cannot be differentiated. Preceding both of these techniques were inertial impaction devices, using centrifugal force, cascading orifices, or counterflow for size discrimination. Centrifuges and cyclones collect the particles, which cross streamlines as the air is forced into a graduated rotation. In a cascade impactor successive nozzle diameters decrease thus increasing air velocity and capturing ever smaller particles. Nozzle diameters are designed for the sizes of interest. Counterflow, or virtual impactors only collect particles with enough inertia to resist the counterflow. In all of these techniques, the collected particles must be analyzed using standard filter and microscopy techniques.

Mass

All aerosol mass measurements rely on aerosol capture either on filters or oscillating microbalances. All but one are gravimetric, comparing the weight of exposed and unexposed substrate. The exception uses the attenuation of a beam of β -particles (electrons) irradiating exposed and unexposed substrate. The attenuation is directly proportional to mass. There are several systems using sensitive oscillating devices such as microbalances, which provide direct, real time, mass measurements as opposed to the delayed analysis of gravimetry and β -ray attenuation. These instruments measure changes in oscillation frequency of sensitive elements as mass is accreted. The tapered element oscillating microbalance mounts a replaceable aerosol collector on the tip of the tapered element, which is oscillated by an electric field. The resonant frequency of oscillation changes as mass accumulates on the filter, through which air is flowing. Similar principles apply to piezoelectric crystal microbalances. The resonant frequencies of the metal-coated quartz crystals decrease as mass is deposited. Particles are deposited, by either electrostatic precipitation or inertial impaction onto the metal, which can become inefficient for larger solid particles due to rebound. The frequency of exposed crystals are referenced to an unexposed crystal at the same temperature, pressure, and humidity. Size differentiated mass can be obtained from these instruments by coupling them with inertial impactors or other size selecting techniques. A variation of the quartz crystal microbalance involves a technique to increase oscillation frequency from 10 to 100 MHz. This is called a surface acoustic wave and increases mass sensitivity by a factor of a thousand.

Surface Area and Shape

Aerosol surface area is of primary interest when considering the impact of aerosol on either atmospheric chemistry or radiation.

Most commonly, surface area is derived from other fundamental measurements such as size distribution. There are, however, several direct ways to measure surface area. These rely on a tracer colliding with and sticking to the particles. Since the collision rate depends on surface area, a measure of the number of tracers collected is a measure of the aerosol surface area, at least the 'active' surface area available for either chemical or radiative interactions. Electrical, radioactive, and photon tracers are used. For electrical tracers, a corona discharge is used for a source of unipolar ions in concentrations high enough for their collection by aerosol through Brownian motion. The charged aerosols are then captured on an impactor stage, or filter, in a Faraday cage, and the very low current (fA) measured. The current is directly proportional to the ions collected, and thus surface area. If a cascade impactor is inserted prior to particle collection, then size resolution of the surface area is available. Alternatively number distributions can be determined if the average number of charges collected per particle size is known. The epiphaniometer works similarly but uses the decay of actinium (^{227}Ac) to radon (^{219}Rn) to lead (^{211}Pb) to produce a source of ^{211}Pb atoms dispersed in a chamber through which the particles flow. Downstream of the chamber with the lead atoms, the aerosol is collected on a filter below an α particle detector. The number of ^{211}Pb atoms collected is measured through their α -decay to ^{207}Pb . The photoelectric aerosol sensor uses UV photons to irradiate aerosol samples. UV photons colliding with a particle are energetic enough to create free electrons from electrons near the particle surface. As the particles lose electrons they become charged. The free electrons ionize nearby gas molecules and move away from particles $<1\text{ }\mu\text{m}$. The gas ions are trapped and the charged particles collected on a filter in a Faraday cage from which the very low current is measured.

Solid particle shape is another of the difficulties of aerosol measurement. Shape affects surface area and therefore chemistry, radiational interactions, and aerodynamic drag, and thus any measurement or process depending on these properties. Shape is often accounted for by adding an adjustable shape factor used to reconcile disparate measurements of other properties. One direct measurement is through microscopy, which is useful to present the challenges which shape can provide. The depolarization of polarized light sources from backscattersondes is another option for particles $>\text{about } 1\text{ }\mu\text{m}$ to indicate the extent of nonsphericity of the particles.

Optical Properties

The optical properties of aerosol form a significant part of several of the instruments already discussed; however, aerosol scattering, absorption, and their sum, extinction, are also measured directly with ensemble instruments. Scattering is measured with a nephelometer, which consists of a monochromatic light source, sampling chamber, and photodetector. Light scattered from aerosol and gas in the sampling chamber is collected over an angular range of ~ 7 to $\sim 170^\circ$. Filtered and ambient air are alternated in the sample chamber to account for variations due to air density and illumination. Some instruments include a shutter to block the forward scatter, so that both total scatter and backscatter are measured. Multiwavelength instruments are available. The backscattersonde, usually deployed on balloons

or aircraft, consists of a pulsed light source and receiving optics focused on the light backscattered from 30 to 50 m from the instrument. Light sources can be xenon flash lamps, lasers, or light emitting diodes. Pulsed light sources allow comparisons of stimulated and ambient backscatter and provide instrument background. For broadband sources, detector filters provide the wavelength dependence. For monochromatic sources, several wavelengths are used. For polarized light sources, depolarization provides particle shape information. Measurements of absorption have already been discussed in the descriptions of the filter-based black carbon instruments and the photoacoustic spectrometer, while extinction measurements have been described using cavity ring-down instruments.

Nucleative Properties

Aerosols play pivotal roles in the hydrologic balance of the atmosphere through their role as cloud condensation nuclei (CCN) and ice nuclei. Without particles we would have neither clouds nor atmospheric ice. CCN counters are similar to CN counters, with the exception that the working fluid is water and the supersaturation is much lower and more carefully controlled. Most CCN counters are based on thermal gradient diffusion chambers, which consist of parallel water saturated surfaces held at different temperatures. Since the diffusion rates of temperature and water between the surfaces differ, supersaturated regions develop in the interior. Controlling the wall temperatures controls the chamber supersaturations in the range 0.05–2.0%. Static thermal diffusion chambers operate by holding air samples drawn into the sample chamber at a single supersaturation for approximately 20 s. Scattering from the cloud of droplets is associated with a number concentration through calibration. Continuous flow thermal diffusion chambers can be operated at several supersaturations simultaneously, by maintaining several discrete temperature differences across the plates at different points in the sampling chamber. Aerosol particles are exposed to increasing supersaturations and so increasingly smaller particles will activate and grow. The droplet size at the end of the chamber, measured with a single particle optical counter, is an indication of droplet growth, which is directly related to the critical size and supersaturation of the CCN. These instruments provide a CCN supersaturation spectrum from single aerosol samples. Static diffusion chambers must adjust plate temperatures between samples to provide a supersaturation spectrum.

Because of their highly active role in precipitation, ice nuclei are even more interesting than CCN, are even harder to measure, and are much more rare. While CCN may constitute 0.1 of the ambient aerosol number concentration, ice nuclei constitute usually $<10^{-4}$ of the ambient aerosol population. There are only a few ice nuclei counters available. They all work on the same principle, mixing the aerosol into a water supersaturated environment, cooling the resulting cloud droplets, which now contain the aerosol, and counting the droplets which freeze. Differences occur due to chamber geometry and orientation, and ice particle detection methods ranging from manual to automatic. The first automated instrument detected ice acoustically as the relatively large ice particles exited a small opening. More recent instruments use optical particle counters. All the instruments primarily measure particles, which act as

condensation freezing nuclei. Instruments to measure deposition or contact ice nuclei are not available.

Nucleated Particles

Completing the contribution of particle measurements to our understanding of the hydrologic cycle are instruments to measure cloud droplets and ice particles. These instruments are optical and use either forward Mie scattering for cloud droplets, or geometric optics to create shadowgraphs of the particles, for ice. The sampling volumes must be adjusted for the different size ranges of interest and thus several instruments are required to cover the complete spectrum. These optical instruments have completely replaced earlier approaches, relying on impaction on films and microscopy. Because of the large particles involved they suffer from edge effects, out of focus images, and false images (*see Clouds and Fog: Measurement Techniques In Situ*).

Synopsis

Water vapor is central to defining the unique properties of the Earth's atmosphere. Despite its importance, it has proven very difficult to measure accurately, especially at the low concentrations encountered in the upper troposphere and lower stratosphere (UTLS). This article offers an explanation of the techniques employed by the current generation of *in situ* sensors designed to measure water vapor in the UTLS. These techniques can be classified into five principal types: frost point hygrometer; photo-fragment fluorescence spectrometer; infrared absorption spectrometer; chemical ionization mass spectrometer; and capacitance hygrometer. Descriptions of a representative set of individual instruments that utilize each technique are also provided.

Introduction

Water vapor is one of the most important atmospheric trace gases. It plays a central role in defining the unique chemical, dynamical, and radiative properties of the Earth's atmosphere. It is also a critical component of Earth's climate system. Water vapor absorbs throughout the infrared (IR) region of the electromagnetic spectrum and as a result is the dominant greenhouse gas. Furthermore, because it can condense into both liquid and solid phases, it is the critical element for aerosol and cloud formation, even at stratospheric altitudes.

Despite comparatively low concentrations in the upper troposphere and lower stratosphere (UTLS), water vapor in this region of the atmosphere has the potential to influence human health and well-being through (1) its response to greenhouse gas forcing and its consequent climate impact, and (2) its effect on the recovery of stratospheric ozone, which moderates the flux of ultraviolet radiation reaching the Earth's surface. Increases in water vapor concentrations in the UTLS lead to radiative cooling at these levels and induce warming at the surface (e.g., Forster and Shine, 1999, 2002; Held and Soden, 2000). The recent analyses of Solomon et al. (2010) and Dessler et al. (2013), for example, suggest that warming at the Earth's surface may be sensitive to sub-ppmv changes in water vapor in the lower stratosphere. Additionally, water vapor is integral to stratospheric chemistry. It is the dominant source of OH in the lower stratosphere (Hanisco et al., 2001), and increases in water vapor concentrations can promote stratospheric ozone loss by raising the reactivity of several key heterogeneous reactions as well as by promoting the growth of reactive surface area, e.g., (Anderson et al., 2012; Drdla and Muller, 2012; Kirk-Davidoff et al., 1999).

This article offers a basic explanation of the principal techniques employed for the *in situ* detection of water vapor in the UTLS, followed by brief descriptions of a representative set of individual instruments that utilize each technique. The measurement techniques can be classified into five principal types: frost point hygrometer; photo-fragment fluorescence spectrometer; IR absorption spectrometer; chemical ionization mass spectrometer; and capacitance hygrometer. In addition to water vapor, some of these instruments have been designed to measure total water, i.e., the combination of water in its gaseous

and condensed phases, as well as the isotopologues of water, e.g., HDO and H₂¹⁸O. Table 1 lists each individual instrument discussed here, and enumerates the technique utilized for water vapor detection, the airborne platform(s), the sampling strategy, target measurement, and a selection of intercomparison campaigns in which each instrument has participated. More thorough coverage of instrumental details, calibration and validation procedures, and analysis of acquired data are available in the cited references. It is important to recognize that no single measurement method is guaranteed to be more accurate or precise than any other, and no method is intrinsically free of systematic errors and uncertainties.

Measurement History

Water in the Earth's atmosphere has proven very difficult to measure accurately. This is largely due to the fact that atmospheric concentrations vary from a few percent at the surface to a few ppmv in the UTLS. The propensity for water to adhere to surfaces also makes it especially challenging, as any surface upstream of the detection region can be a source for water that can contaminate the ambient sample. Such surfaces include aircraft skin, if the instrument inlet is not out of the boundary layer of the aircraft, or water shedding off of a balloon on ascent, for those instruments carried aloft by balloons, as well as instrument ducting. Similarly, any path in a laser absorption experiment between the laser source and the detector that is not explicitly part of the detection volume can contain water that can contaminate or bias the measurement. Finally, the adaptation of instrumentation to moving platforms and the wide range of ambient conditions – pressures ranging from 1000 hPa to less than 50 hPa, and temperatures ranging from ~280 to ~180 K – can introduce sources of uncertainty not encountered in controlled laboratory settings.

Early comparisons of water vapor measurements in the stratosphere exhibited large discrepancies. The World Meteorological Organization report published in 1985, titled Atmospheric Ozone, shows results of what were then state-of-the-art *in situ* and remote water vapor measurements (WMO, 1985). Differences among the *in situ* instrumentation from 14 km to >30 km are on the order of 1.0 ± 0.5 ppmv, equivalent to

Table 1 *In situ* water vapor instruments with their measurement method, respective platform, sampling technique, target measurement, and selection of intercomparison campaigns in which they have participated

Instrument acronym	Measurement principle	Platform	Sampling	Molecule	Comparison campaign ^a

approximately 15–50% depending on the ambient mixing ratio. These data were acquired by balloon-borne and aircraft-borne instrumentation during two targeted international water vapor intercomparison launches out of Palestine, Texas, in 1981 and 1983. In both cases, data from Lyman- α photo-fragment fluorescence instruments were biased high relative to data from the frost point sensors.

Since that time, there have been significant advances in instrument design, the development of new measurement technologies, as well as improvements in calibration and validation methodologies. The results of a comprehensive analysis of intercomparison data obtained prior to 2000 are published in Chapter 2 of the Stratospheric Processes and their Role in Climate (SPARC) Assessment of Upper Tropospheric and Stratospheric Water Vapor (SPARC, 2000). The report includes intercomparisons of satellite, aircraft, balloon-borne, and ground-based water vapor instrumentation. Discrepancies in the critical range of 1–10 ppmv in the 60–100 hPa layer (shown in Table 2.7 of the report, and bottom panel of Figure 2.72) exhibit a range for the comparison of the

measurement means of approximately $\pm 15\%$, with the full range extending to approximately $\pm 30\%$. The two instruments at the highest end of the comparisons are aircraft-borne *in situ* instruments (photo-fragment fluorescence and IR absorption hygrometers), with the balloon-borne *in situ* instruments (frost point sensors) positioned near the middle. (SPARC (2000) is an excellent resource. In addition to the intercomparison analysis, it motivates the need for accurate and precise water vapor measurements, provides descriptions of a comprehensive suite of *in situ* as well as remote instrumentation, and summarizes the state of knowledge regarding the factors controlling the distribution and variability of water vapor in the UTLS.)

Despite this apparent improvement in instrument agreement, differences of a larger magnitude, i.e., ~ 1.5 ppmv or equivalently approximately 50–70% at the water vapor minimum near the tropical tropopause, were once again documented during coordinated intercomparisons of balloon and aircraft instrumentation during the Costa Rica Aura Validation Experiment (CRAVE) campaign operated out of

San Jose, Costa Rica, in February 2006 (Jensen et al., 2008; see also Figure 1 of Fahey et al., 2014). These differences, which are greater than the stated instrumental uncertainties, provided the motivation for an international laboratory intercomparison campaign, i.e., the first Aqua Validation and Instrument Tests (AquaVIT-1), which was conducted at the AIDA aerosol and cloud simulation chamber at the Karlsruhe Institute of Technology, Germany, in October 2007. The results of the laboratory campaign among a core group of instruments showed good agreement, of about $\pm 10\%$ ($\pm 1\sigma$) for mixing ratios between 10 and 150 ppmv, and fair agreement of $\pm 20\%$ ($\pm 1\sigma$) for the region of most interest between 1 and 10 ppmv. The implication is that the substantially larger differences observed during some *in situ* intercomparisons may stem from factors associated with instrument integration onto moving platforms or arise in response to the inherent differences between the laboratory and ambient environments (Fahey et al., 2014). (Fahey et al., (2014) offer a thorough overview of the AquaVIT mission goals, an explanation of the structure of the blind intercomparison, which can function as a template for future efforts both in the laboratory and in *in situ*, a discussion of the analysis methods applied and results, as well as descriptions of the participant instruments submitted by the instrument teams.)

The most recent results from *in situ* comparisons of aircraft-borne and balloon-borne instrumentation acquired during the Mid-latitude Airborne Cirrus Properties Experiment (MACPEX) operated out of Houston, Texas, during the spring of 2011, once more showed improved agreement, with differences consistently < 1 ppmv (Rollins et al., 2014). (Rollins et al. (2014) provide the most recent discussion and analysis of an *in situ* water vapor intercomparison effort. Many of the same instruments that participated in AquaVIT-1 were present during the MACPEX mission.) However, the tendency for the frost point balloon instruments to measure lower than independent aircraft instruments persists, and the large variability in agreement over the past two decades is cause for concern.

These discrepancies prevent a rigorous understanding of the processes that control the distribution and phase of water vapor throughout the upper troposphere and stratosphere (Peter et al., 2006). With disagreements among water vapor measurements, on the order of 1–2 ppmv in the UTLS, the atmospheric chemistry and climate community cannot reliably model the chemical and radiative properties of this region, or predict the response of this region to anthropogenic climate forcing. Several studies have shown that the discrepancy among measurements is too large to constrain the role of different hydration and dehydration mechanisms, e.g., cirrus cloud formation and subsequent dehydration in the tropical upper troposphere (Jensen et al., 2005, 2008; Krämer et al., 2009; Weinstock et al., 2009). For example, model validation is dependent upon which data set is chosen. Moreover, the controversy among the *in situ* instruments fails to support a robust satellite data set, and the overall uncertainty is too large to unambiguously detect, quantify, and attribute trends in water vapor concentrations, particularly at the level of $\sim 1\%$ per year (0.04 ppmv per year) (Oltmans and Hofmann, 1995; Oltmans et al., 2000; Scherer et al., 2008; Hurst et al., 2011). These concerns highlight the need for measurements with high precision and unassailable accuracy.

Frost Point Hygrometer

Principle of Operation

Most standard frost point hygrometers use a chilled-mirror technique, in which a layer of dew or frost is formed on the surface of a small mirror in contact with ambient air. Changes in the frost layer are detected optically, with photo-detectors sensing light, typically from a light-emitting diode, that is scattered off the frost layer. The mirror temperature is actively controlled, heated, or cooled as necessary, to maintain a constant frost layer, i.e., a constant signal on the photo detectors. Depending upon the instrument type, the mirror temperature is controlled with either a mechanical (Stirling-type cooler) or a thermoelectric (Peltier) device, or by actively heating a resistive element against passive cooling with a cryogenic bath. In the cryogenic devices, the mirror is connected to the bath by a rod of high thermal conductivity. Assuming the frost layer is held in thermodynamic equilibrium with water vapor in the air passing over the mirror, measurements of the mirror's temperature obtained with a thermistor or platinum resistance thermometer embedded in, or near, the mirror surface are used to determine the partial pressure of water vapor in the sample. One of several variations of the Clausius–Clapeyron equation may be used to derive the equilibrium vapor pressure of water vapor over ice as a function of temperature (The equation has not been standardized in the measurement community. Though the differences in derived mixing ratio are often approximately $< 1\%$, it is important to be aware of which equation is used by each measurement system.) (Murphy and Koop, 2005). Ambient water vapor mixing ratio is calculated from the derived vapor pressure and simultaneous measurements of ambient pressure and temperature.

The accuracy and precision of this technique may depend upon several factors, among them: (1) the integrity of the ambient sample, i.e., that water from the balloon or other surfaces upstream does not contaminate the flow through the device, or alternatively, that water is not condensed out on the walls upstream of the mirror; (2) the assumption that the frost layer achieves equilibrium with ambient water vapor as the sensor ascends and descends through the atmosphere; (3) the assumption that the observed condensation temperature is not altered by atmospheric impurities (e.g., nitric acid or other water-soluble contaminants); (4) the accuracy of the mirror surface temperature, which is dependent upon the calibration of the primary temperature device, as well as the assumption that the measured temperature accurately represents the mirror surface temperature, i.e., that there are no significant temperature gradients; (5) the sensitivity of the optical sensor and feedback electronics to changes in the frost layer; (6) the sensitivity of the optical feedback to solar scatter; and (7) the accuracy of the simultaneous measurements of ambient temperature and pressure that are used to determine mixing ratio. Furthermore, the spatial and temporal resolution of the measurements are influenced by the time response and efficiency of the frost layer/mirror temperature control loop, changes in ambient humidity, and the ascent or descent rate of the balloon, or speed of the aircraft. The specific instruments listed here have successfully addressed these concerns, albeit in different ways, and data from frost point devices constitute one

of the longest continuous records of accurate and precise water vapor data in the UTLS.

Frost point hygrometers do not rely on routine or regular calibration, that is, the empirical determination of their detection sensitivity through comparison with external water vapor standards. However, comparison with a reference standard is recommended for assessing the sensor's susceptibility to sources of systematic error. Ultimately, the accuracy of the frost point measurements is tied to the accurate determination of the mirror temperature. It is imperative, therefore, that the mirror thermistors be carefully calibrated, i.e., that their resistive response to temperature be determined over the relevant temperature range.

The NOAA Cryogenic Frost Point Hygrometer

The National Oceanic & Atmospheric Administration (NOAA) Earth System Research Laboratory's (ESRL) Global Monitoring Division (GMD) frost point hygrometers (FPHs) are balloon-borne instruments that provide continuous measurements of water vapor from near the surface to the middle stratosphere. Their heritage extends back to the Naval Research Laboratory in Washington, DC (Mastenbrook and Dinger, 1961), and they have provided a long history of water vapor profiles in the UTLS and have contributed significantly to understanding stratospheric water vapor (e.g., Hurst et al., 2011, and references therein). Approximately 500 launches of the NOAA FPH from Boulder, Colorado, from April 1980 through February 2010 have yielded more than 300 water vapor vertical profiles with reliable stratospheric data, providing information on water vapor trends and variability throughout the upper troposphere and middle stratosphere (Hurst et al., 2011; Kunz et al., 2013). The present generation has a stated total uncertainty of ± 7 – 10% arising from systematic uncertainties in the determination of the frost temperature and total pressure ($\sim 0.5^\circ\text{C}$ and 0.5 hPa , respectively) (Vömel et al., 1995; Vömel et al., 2007a).

The FPH instruments operate with a cryogenic bath, and regulate the mirror temperature with a resistive heater connected to a microprocessor-controlled feedback loop. The system allows for both fast heating and cooling rates, and thus good time response and vertical resolution. Ambient air is drawn in through a clean 18 cm long stainless steel tube, designed to eliminate contamination. Flow velocities through the sample tube are estimated to be roughly half the velocity of the balloon. For ascent velocities of 5 m s^{-1} mass flows through the tube are ≥ 10 standard liters per minute (slm) up to the tropical tropopause level, and decrease to ~ 5 slm at 20 km. It is expected that self-contamination from the inlet tubes at these velocities and mass flows is minimal (Vömel et al., 2007a). Contamination from the balloon itself can occur on ascent, and is sometimes evident between 20 and 25 km. Data showing evidence of contamination are identified and removed.

The Cryogenic Frost Point Hygrometer

The cryogenic frost point hygrometer (CFH) was developed during 2003–04. It uses the same fundamental measurement principle and design as the NOAA/ESRL/GMD FPH. Like the FPH, it is a small balloon-borne instrument that provides continuous vertical profiles of water vapor from the surface to

approximately 25–28 km. At the time of its development, a number of features were introduced to reduce the power consumption, weight, cost, and operator skill required by the older generation FPH. In its current configuration, which is manufactured and sold by Droplet Measurement Technologies (DMT), the instrument package includes the CFH, an electrochemical concentration cell ozone sonde, a Global Positioning System, and a radiosonde. The radiosonde provides *in situ* temperature and pressure data as well as serving as the data transmitter. Details of the instrument and an analysis of its measurement results are contained in Vömel et al. (2007a). The stated accuracy of the CFH is better than $\pm 4\%$ in the lower troposphere, and less than or equal to $\pm 9\%$ in the vicinity of the tropopause, and $\pm 10\%$ in middle stratosphere (<http://www.dropletmeasurement.com/sites/default/files/Brochures/CFH.pdf>, recovered 27 February 2014).

Comparisons between an older generation FPH and the then newly developed CFH instrument were executed in June 2005. Four soundings in total (two each) were acquired on different days. Comparisons of descent profiles of the two instruments show agreement well within the instrumental uncertainty throughout the stratosphere. The data from these soundings show no evidence of a bias in either instrument. More recently, from June 2008 to February 2009 there were five soundings launched of Boulder, Colorado, with both the CFH and present generation FPH on the same balloon. The mean difference between stratospheric water vapor measurements by the two instruments on these flights was $0.1 \pm 0.3\text{ ppmv}$, or $\sim 2 \pm 6\%$ of the mean stratospheric water vapor mixing ratio. For more comparisons of CFH with other UTLS hygrometers, and a detailed discussion of using CFH in support of Aura Microwave Limb Sounder (MLS) version 1.5 and version 2.2 validation efforts refer to the following references (Read et al., 2007; Vömel et al., 2007a,b).

Laboratory versions of both the FPH and CFH instruments have been developed, equipped with the same or similar thermal, optical, and electronic components as the flight hygrometers, and packaged within a vacuum housing. This modification allows them to interface to a controlled water vapor source operated at relevant atmospheric pressures.

The LMD-CNRS Frost Point Hygrometers

The Laboratoire de Météorologie Dynamique du Center National de Recherche Scientifique (LMD-CNRS) has developed a frost point hygrometer for use on aircraft, traditional balloon-borne payloads, and long duration (Montgolfier Infra-Rouge, MIR) balloon-borne payloads. The principle of operation of the three airborne versions is the same, with differences only in (1) how the frost point temperature is controlled, i.e., Peltier thermoelectric device versus cryogenic cooling, and (2) how air is brought to the mirror surface. Calibration and tests of the instruments are routinely performed with a system that allows the generation of frost point temperatures down to -90°C , from 1000 to 20 hPa, simulating the conditions encountered during balloon and aircraft flights. Comparisons between the frost point produced by the calibration device and the corresponding frost point measured by the flight hygrometers typically show agreement to within the precision of the hygrometer. A discussion of the family of LMD hygrometers, operational details, the

calibration procedure, and a list of publications utilizing LMD data is available online at http://ether.ipsl.jussieu.fr/etherTypo/fileadmin/files/ELHYSA/info_ELHYSA.pdf, recovered 27 February 2014.

Photo-Fragment Fluorescence

Principle of Operation

In the photo-fragment fluorescence technique, water vapor is dissociated with vacuum ultraviolet (VUV) radiation, typically Lyman- α ($\lambda_{\alpha} = 121.6$ nm). Some of the OH photo-fragments are formed in their first excited electronic state (OH^*), and their subsequent fluorescence, near 310 nm, is proportional to the number density of water vapor in the detection volume. The following equation demonstrates this proportionality: $S_{\text{OH}^*} = [\text{H}_2\text{O}] \cdot C_{\text{flr}}$. In this equation, S_{OH^*} is equal to the normalized net fluorescence signal detected, e.g., counts per second, $[\text{H}_2\text{O}]$ represents the water vapor number density in the detection volume with units of ($\# \text{ cm}^{-3}$), and C_{flr} is the empirically determined density-dependent constant of proportionality. At moderate and high ambient pressures, i.e., $\geq \sim 100$ hPa, most of the excited state OH^* radicals are quenched by collisions with air molecules at a rate proportional to air density, $[\text{M}]$ ($\# \text{ cm}^{-3}$). Thus, in the troposphere and lowermost stratosphere the fluorescence signal is almost directly proportional to the ambient volume mixing ratio, e.g., $S_{\text{OH}^*} \sim [\text{H}_2\text{O}]/[\text{M}]$.

The accuracy and precision of this technique depend upon several factors, among them (1) the delivery of uncontaminated ambient air to the detection region; (2) the accurate calibration of the instrument sensitivity, represented by the density-dependent proportionality constant C_{flr} that relates the detected fluorescence counts to the water vapor concentration; (3) the applicability of the calibration, determined in the laboratory, to the *in situ* environment; (4) the accurate measurement of the VUV lamp intensity used in the normalization; (5) the rejection by the detector of background UV radiation from the Sun as well as from the VUV light source in the region of the fluorescence signal (290–350 nm); (6) the assumption that there are no other sources of VUV stimulated fluorescence; and (7) the accuracy of the simultaneous measurements of temperature and pressure that are required to determine mixing ratio. When these criteria are met, photo-fragment fluorescence can provide accurate and precise measurements of water vapor from the middle troposphere to over 20 km with a time resolution of ~ 1 Hz or better.

As noted above, the photo-fragment fluorescence detection method requires calibration, i.e., the empirical determination of the quantitative relationship between normalized net fluorescence counts and known water vapor mixing ratios over a range of temperatures and pressures that are representative of the atmospheric environment. The accuracy of the photo-fragment instruments critically depends upon the accuracy with which the mixing ratios generated in the laboratory are known. Different photo-fragment hygrometers have chosen different reference standards. Again, no single reference standard is fundamentally preferable to another, and the final estimate of uncertainty for the photo-fragment sensors, typically ± 5 –10% in mixing ratio, depends more upon the details

of the laboratory calibration procedure than on the choice of standard.

Fast *In Situ* Hygrometer Instruments

The fast *in situ* stratospheric hygrometer (FISH) instruments, which utilize the Lyman- α photo-fragment fluorescence technique, were developed at the Forschungszentrum Jülich, Germany (Zöger et al., 1999). A modular design has allowed FISH to be deployed on different aircraft (Lear Jet, Geofizika, Falcon, and NASA's WB-57), as well as balloon-borne payloads. Furthermore, with the addition of a heated inlet, FISH can operate in an enhanced total water (vapor + amplified condensed phase water) mode. The accuracy of the current design is typically $\sim \pm 6\%$, $+0.15$ ppmv, with a precision of $< \pm 0.1$ ppmv at 1 Hz (Fahey et al., 2014; Rollins et al., 2014; and references therein).

FISH consists of a closed, vacuum-tight fluorescence cell made of black glass mounted in a larger stainless steel cell designed to eliminate both scattered light and outgassing from dead volumes, a Lyman- α radiation source, a photo-multiplier tube (PMT) in photon-counting mode, two detectors to monitor the VUV lamp intensity, one across from the lamp, and the other positioned equidistant from, but at right angles to the lamp, and a mirror drive to control the measuring cycle, e.g., the determination of the fluorescence signal, the background count rate, as well as the lamp intensity. The water vapor mixing ratio of the sample is determined from the net normalized fluorescence signal and the empirically derived calibration coefficients that define the instrument sensitivity.

The nature of the inlet design varies depending upon the aircraft and whether or not the instrument is measuring vapor only or enhanced total water. However, the inlet is always designed to be well outside the aircraft boundary layer. In the enhanced total water configuration, the inlet is forward facing and samples particles anisokinetically, i.e., the number of particles in the sample is enhanced relative to the ambient particle number density. The amplification factor depends upon particle size and can be calculated. In this configuration, the inlet line is ~ 2.5 m long and consists of ~ 2 m of 1 cm inner diameter heated stainless steel tubing ensuring the complete vaporization of the sampled particles. Flow rates through the instrument are 10–50 l per minute, and decrease with altitude.

Calibration of FISH occurs frequently during mission deployments. The calibration system consists of a humidity generator and a commercial frost point device (MBW-DP30), which serves as the laboratory reference instrument (Zöger et al., 1999; Meyer, 2008). Calibrations are executed over a range of pressures (approximately 80–500 hPa) and mixing ratios (1–500 ppmv) to cover the relevant range of the *in situ* measurements. The MBW-DP30 is calibrated by the manufacturer and is traceable to international standards.

Harvard Water Vapor and Harvard Total Water Instruments

Versions of the Harvard University water vapor Lyman- α photo-fragment fluorescence instrument (HWV) have measured water vapor *in situ* in the UTLS for over 20 years (Schwab et al., 1990; Weinstock et al., 1994; Hintsa et al., 1999). The present design, intended for deployment on NASA's

ER-2 and WB-57 aircraft, was developed in 1998. A companion Harvard total water (vapor + condensed phase) (HTW) instrument was developed in parallel and both instruments have been flying missions since 2001 (Weinstock et al., 2006a,b). The most recent configuration of HWV includes both the Lyman- α instrument discussed here and an independent instrument, the Harvard Herriott Hygrometer (HHH) discussed in the IR absorption section, which is located upstream (Sargent et al., 2013). HWV has an achievable precision of ~ 0.1 ppmv at 1 Hz, and an accuracy of $\sim \pm 5$ –8% based upon laboratory calibrations, with a maximum additional bias of < 0.3 ppmv (Weinstock et al., 2009; Rollins et al., 2014; and references therein).

All versions of the Harvard Lyman- α instrument utilize 121.6 nm radiation from a sealed radio-frequency discharge lamp to photo-dissociate water vapor in an internal duct, with the resulting OH* fluorescence collected at right angles to the duct and the Lyman- α light source through a stack of optical filters and detected with a PMT. A cell containing flowing dry air is used to filter unwanted VUV radiation from the lamp, and a coated magnesium fluoride narrow bandpass filter (incorporated in 2008) is used to preferentially allow 121.6 nm light into the detection volume. This optic eliminates background signal from the lamp at the near UV fluorescence wavelengths. An antireflection coated quartz window within the filter cell is cycled in and out of the Lyman- α lamp beam to enable measurement of any nonfluorescent background signal from either the lamp or solar scatter in the duct. The Lyman- α lamp intensity is continuously monitored with a VUV vacuum photodiode mounted across the duct and opposite the lamp. This signal is used to normalize the net fluorescence counts. Conversion of normalized net counts to water vapor number density in the duct is accomplished with the empirically determined calibration constants. The determination of the ambient mixing ratio is achieved via pressure and temperature measurements acquired by a pitot tube and thermistors mounted immediately downstream of the detection region.

A rear-surface coated magnesium fluoride (MgF_2) mirror adjacent to the diode reflects some of the VUV radiation back across the duct to a second diode, allowing for the simultaneous measurement of water vapor by direct absorption in the mid- to upper troposphere. This provides a means of independently verifying the fluorescence measurement *in situ*.

In the current version of HWV, air is ram-fed through a $\sim 9 \times 10$ cm aluminum duct in the nose of a pod mounted under the wing of NASA's WB-57 or ER-2 aircraft. The inlet extends forward of the pod so as to sample air unperturbed by the aircraft or the wing. The laminar core of the primary flow is sampled downstream through a $\sim 5 \times 5$ cm square secondary duct. The secondary duct directs the flow through an aerodynamically designed light trap to exclude solar scatter, and on to the Lyman- α detection axis. Flow velocities of $\sim 70 \text{ m s}^{-1}$ are maintained through the detection region for fast time response and to prevent contamination of the sample due to water outgassing from walls upstream. Under normal conditions, a downstream throttle valve is fully open to facilitate fast flow. For diagnostic purposes, the valve is periodically throttled to slow the flow and test for potential contamination.

The HTW instrument, which utilizes the same detection method as HWV, integrates in a pallet that flies in the belly of

the WB-57 aircraft. Air is drawn through a 1 cm diameter forward facing inlet positioned about 1 m from the skin of the aircraft to avoid contamination by either the aircraft boundary layer air or ice particles bouncing off the skin of the aircraft. Isokinetic flow through the inlet is maintained via real-time control of a roots pump located downstream of the detection axis. This ensures that air is brought into the instrument without perturbing the ambient particle density. Approximately 600 W of heat distributed both in the flow and along the ducting ensures that ice particles $\leq 50 \mu\text{m}$ in diameter are fully sublimated upstream of the detection region.

The Harvard Lyman- α instruments are calibrated in the laboratory before, during, and after mission deployments by flowing known amounts of water vapor in air through the detection axes. The air–water vapor mixtures are prepared by diluting saturated air, generated using a dual-stage bubbler apparatus, with a primary flow of dry air. The concentration of the water vapor added to the calibration duct is independently verified by a direct absorption measurement at 121.6 nm. Calibrations are executed over a range of mixing ratios, pressures, and temperatures representative of the UTLS. The combination of laboratory calibrations and in-flight diagnostics sets the expected ± 5 –8% accuracy of HWV (Weinstock et al., 1994; Hints et al., 1999; Weinstock et al., 2006a, 2009). The maximum potential bias is empirically constrained to be < 0.3 ppmv by measuring the mixing ratio in nitrogen gas delivered from a liquid nitrogen Dewar or very dry air in the laboratory (Hints et al., 1999).

Fluorescent Advanced Stratospheric Hygrometer Instruments

The fluorescent advanced stratospheric hygrometer for balloon (FLASH-B) instrument is a compact lightweight Lyman- α photo-fragment fluorescence sonde developed at Central Aerological Observatory (CAO), Russia, for balloon-borne water vapor measurements in the UTLS (Yushkov et al., 1998, 2001). FLASH-B has flown successfully in a number of balloon campaigns. Some of these campaigns have included simultaneous measurements by independent instrumentation, e.g., FPH and CFH (Vömel et al., 2007a; Khaykin et al., 2013). The expected precision of FLASH is 5.5% for a 4-s integration time, with a calibration uncertainty of $\sim 4\%$ in the 3–100 ppmv range. The total uncertainty of the measurement is estimated to be $\sim \pm 10\%$ for mixing ratios > 3 ppmv, and $\sim \pm 20\%$ for mixing ratios < 3 ppmv (Fahey et al., 2014; and references therein).

The instrument uses a current-stabilized hydrogen discharge lamp filled with a mixture of hydrogen and helium at a total pressure of 10 hPa to provide Lyman- α radiation for the photo-dissociation of water vapor. The lamp utilizes a specially fabricated MgF_2 window to suppress wavelengths in the 270–320 nm band arising from both stray helium emission and hydroxyl emission from the lamp. A PMT run in photon counting mode detects the resulting OH fluorescence through a narrow band interference filter in the fluorescence spectral region, i.e., 308–316 nm.

FLASH-B uses an open layout where the detection optics look directly at the sky (Khaplanov et al., 1992). Accordingly it is only suitable for nighttime measurements. The intensity of the fluorescent light sensed by the photomultiplier is effectively directly proportional to the water vapor mixing ratio under

stratospheric conditions (30–150 hPa) with small oxygen absorption (3% at 50 hPa). At pressures greater than 150 hPa, the VUV absorption by oxygen and water vapor is taken into account. The background signal caused by the night sky emissions in the absence of fluorescence is detected by modulating the lamp with a 1 kHz square wave with a 1/8 duty cycle, combined with a synchronous demodulation of the received signal.

A FLASH instrument has also been developed for use aboard the Geofizika highaltitude aircraft (Sitnikov et al., 2007). Generally, the airborne system is nearly identical to the balloon-based version. A closed cell design, however, permits measurements during the day as well as at night. The FLASH instruments are routinely calibrated at CAO. An MBW-373L dew point hygrometer serves as the reference instrument. Calibrations cover the range of water vapor mixing ratios encountered in the UTLS at pressures of 10–1000 hPa.

Photo-Fragment Laser-Induced Fluorescence

Principle of Operation

A photo-fragment laser-induced fluorescence instrument was developed at Harvard University for the simultaneous measurement of H₂O and its heavy isotopologue HDO in the UTLS (St Clair et al., 2008; Wennberg et al., 1994). Unlike the Lyman- α instruments discussed previously, the photolysis and detection are separated significantly in space and time. This instrument uses a high pressure Xenon excimer lamp with maximal output at 172 nm to make ground electronic state OH and OD from the photo dissociation of H₂O and HDO. The OH and OD radicals are subsequently detected downstream via laser-induced fluorescence (LIF) using a tunable pulsed laser near 288 nm. Precision tuning of the laser allows for the selective excitation and detection of both OH and OD. In order to compensate for the relative atmospheric abundance of HDO and H₂O, $\sim 3 \times 10^{-4}:1$, the specific spectral region for this instrument was chosen such that the sensitivity to OD is several orders of magnitude greater than that for OH. The excited OH and OD radicals fluoresce via the same mechanism beginning with collisional relaxation of the selected excited vibrational state followed by the radiative relaxation of the excited electronic state that yields the detected fluorescence signal at ~ 309 nm.

The OH and OD concentrations are directly related to the measured fluorescence signal through the following equation: $(OX) = S_{OX} \cdot C_{OX}$. In this relationship, S_{OX} is equal to the signal collected at the PMT, and C_{OX} represents the empirically determined sensitivity or calibration constant for OH or OD detection. C_{OX} includes terms that account for the fluorescence efficiency of the excited state OH and OD radicals, and the optical collection efficiency of the detection system. The measured concentrations of OH and OD are then tied directly to ambient H₂O and HDO concentrations via a second equation that accounts for the photolysis yield of OH and OD and the chemical loss of OH or OD via the self reaction $OH + HO_2 \rightarrow H_2O + O_2$ that occurs during time between photolysis and fluorescence detection. The overall sensitivity of the instrument to H₂O and HDO is determined via frequent laboratory calibrations with a known water vapor source,

where the initial HDO:H₂O ratio of the liquid water source and the isotopic fractionation that occurs during calibration are well characterized.

The accuracy and precision of this technique depend upon several factors, among them (1) the delivery of uncontaminated ambient air to the detection region; (2) accurate calibration, specifically the determination of the photolysis yield, and careful monitoring of the optical collection efficiency in the laboratory and in flight; (3) the applicability of the calibration, determined in the laboratory, to the *in situ* environment; (4) the assumption that there are no sources of chemical or fluorescence interference; and (5) the accuracy of the simultaneous measurements of temperature and pressure that are required to determine mixing ratio. When these criteria are met, photo-fragment LIF detection provides molecular selectivity, high sensitivity and fast time response, for accurate and precise measurements of water vapor and its heavy isotopologue, HDO, throughout the UTLS.

Harvard ‘Hoxotope’

At present, there is only one instrument that utilizes this detection technique. This instrument, developed at Harvard University, utilizes the same technique and much of the same equipment, e.g., ducting, optics, and electronics, that was developed for the detection of OH and HO₂ radicals in the UTLS aboard NASA’s ER-2 aircraft (Wennberg et al., 1994). The ER-2 ‘HO_x’ instrument was modified in 2004 for the *in situ* measurement of water vapor and its isotopologue, HDO, and acquired the name ‘Hoxotope’. The instrument has flown in several missions over the past decade on NASA’s WB-57, and analyses of the simultaneous H₂O and HDO measurements have been influential in demonstrating the potential importance of convection in hydrating the UTLS (Hanisco et al., 2007). At typical stratospheric values, e.g., HDO = 0.8 ppbv and H₂O = 5 ppmv, the precision in 10 s is ± 0.04 ppbv for HDO and ± 0.02 ppmv for H₂O. Adding all the known uncertainties in quadrature yields an overall calibration uncertainty, and in-flight accuracy, of $\pm 5\%$ for both H₂O and HDO (St Clair et al., 2008).

Hoxotope has flown in both a vapor-only sampling configuration (rear-facing inlet), as well as in a total water sampling configuration (forward-facing isokinetic inlet). In both configurations, the inlet is heated. In the first case, this is to prevent water uptake, and in the second case, it facilitates particle sublimation. Temperature sensitivities of the detection scheme are also minimized by warming the airflow to $\sim 25^\circ\text{C}$ prior to photolysis and detection. A scroll pump, with a maximum displacement of ~ 8 l per second draws air through the instrument, and an actively controlled conductance-limiting pinch valve is used to regulate the pressure within the detection region of the instrument. The instrument pressure is maintained at 15.3 hPa regardless of the ambient pressure. Every component was chosen to minimize stagnant volumes that can retain water and contaminate the sample.

Calibrations of Hoxotope are executed in the laboratory by adding air with a known water vapor concentration directly to the instrument inlet. The pressure and temperature within instrument during calibration are identical to those in flight. Known concentrations of water vapor are prepared by diluting

saturated air, generated using a single-stage bubbler apparatus, with a primary flow of dry air. While this is a robust calibration method for water vapor, the saturated flow is subject to isotopic fractionation. The heavy isotopologue, HDO, preferentially remains in the liquid phase, and the saturated flow is correspondingly light. Consequently, a second method was devised in which liquid water drops are added directly to the dry carrier flow, via a droplet microinjector, where they completely evaporate, thus preserving the initial H₂O to HDO ratio. As expected, the two methods yield nearly identical results for water vapor, but the microinjector water vapor contains more deuterated water than the bubbler water vapor.

IR Absorption

Principle of Operation

Because of its bent molecular structure, a broad range of rotational and vibrational energy states are accessible to gaseous water, and transitions between these states are associated with the absorption of radiation at specific wavelengths in the IR region of the electro-magnetic spectrum. Two O–H stretching vibrations (symmetric and asymmetric) lead to an absorption band centered at 2.7 μm , and the H–O–H bending vibration leads to an absorption band centered at 6.3 μm . Combinations of these primary vibrational modes lead to additional absorption bands throughout the IR region. It is this feature of water vapor that makes it the most important greenhouse gas in Earth's atmosphere, and that makes IR absorption spectroscopy a preferred method for water vapor detection.

The fractional absorption of light at a specific wavelength by an absorbing species, e.g., water vapor, in a gas sample is directly related to the concentration of that species by the Beer–Lambert Law, i.e., $I/I_0 = e^{-\sigma\ell[\text{H}_2\text{O}]}$. In this equation, I_0 and I refer to the intensity or power per unit area of incident light detected in the absence and presence of water vapor respectively, σ is the molecular absorption cross section of water at the incident wavelength with units (cm^{-1} per ($\# \text{ cm}^{-3}$)), ℓ is the distance in cm the light travels through the detection region, and $[\text{H}_2\text{O}]$ is the water vapor concentration in ($\# \text{ cm}^{-3}$), in the detection volume.

Tunable diode lasers in the IR region are used as the narrow band light sources for these measurements because they can be rapidly and continuously scanned over individual spectroscopic absorption features and thus provide a measure of the intensity at the peak of the absorption feature, I , as well as in a nearby region where absorption is negligible, I_0 . Laser tuning is achieved by continuously increasing the current through the laser over a specified range. As the current increases the laser temperature increases causing a change in the output wavelength. Different types of laser are chosen for accessing different spectral features in the IR region, where the choice of spectral region is dictated by the desired measurement sensitivity, other target molecules, e.g., HDO and H₂¹⁸O, and avoiding absorption by species other than the target molecule(s). Similarly, different detectors are chosen to match the selected laser wavelength.

The sensitivity of the measurement is related to the ratio, I/I_0 , and is typically higher for higher water vapor concentrations, as long as the feature is not saturated. For low water

vapor concentrations, like those encountered in the UTLS, the sensitivity can be improved by increasing the path the light travels through the detection region. This is typically done by creating a cavity in which the laser light is bounced back and forth several times between reflective mirrors before it encounters the detector. The Herriott cell, in which two spherical mirrors are positioned opposite one another, is a commonly utilized multiple-pass cell for absorption spectroscopy (Herriott et al., 1964).

In the simplest version of these instruments, i.e., direct absorption, the ambient concentration of water vapor, $[\text{H}_2\text{O}]$, depends solely on the measurement of the signal, I , accurate determination of the background signal, I_0 , and knowledge of the pathlength, ℓ , as well as the absorption coefficient σ . The absorption coefficient is, in turn, a function of the strength and the shape of the specific molecular transition. Determination of σ requires knowledge of the temperature and pressure in the detection volume as well as several additional spectral line parameters. The HITRAN database (<http://www.cfa.harvard.edu/hitran/>), which was expressly created for modeling the IR properties of the atmosphere, is the standard reference for these empirically determined spectroscopic constants. The direct absorption method provides a technique that does not necessitate frequent calibration, that is, the empirical determination of the instrument's sensitivity to water vapor. However, comparison with an external standard is essential for identifying systematic errors and validating instrument performance.

An additional technique, frequently employed when high-sensitivity is required, is harmonic detection. With this technique, a small-amplitude sinusoidal modulation is added to the basic laser scan. The modulation frequency, f , is usually of the order of tens of kHz. The detector signal is then demodulated at a multiple of this frequency, most often at twice the sine wave frequency, or $2f$ (May and Webster, 1993; May, 1998). This method minimizes certain types of electronic and optical noise that can limit the detection sensitivity of the instrument. In contrast to the direct absorption method, however, harmonic detection complicates the determination of the water vapor mixing ratio. Uncertainties in several independent parameters can cause pressure and temperature dependent errors that are difficult to quantify in a second-harmonic spectrometer. Analytical laboratory calibrations are therefore used to derive the appropriate data processing matrices used to convert the modulated $2f$ peak-to-peak amplitude signal, normalized by returned laser power, to measured mixing ratio.

IR absorption measurements have excellent molecular specificity, and have demonstrated outstanding precision and fast time response. The accuracy and precision of this technique depend upon several factors, among them: (1) the delivery of uncontaminated ambient air to the detection region; (2) the minimization of contaminant water in the laser path outside of the detection volume; (3) accurate determination of the temperature and pressure in the detection volume; (4) the accuracy of the spectroscopic parameters in the HITRAN database; and (5) the assumption that instrument performance is robust to the environmental change in going from the laboratory to the atmosphere. Because the water vapor concentration is determined by the ratio of (I/I_0), measurement accuracy is expected to be insensitive to changes in mirror reflectivity, scattering by particles in the duct, or long term changes in laser

power. Direct absorption with a narrow line width source allows the water vapor concentration to be calculated directly from the observed line, known spectroscopic parameters, and simultaneous measurements of the temperature and pressure within the cell. Harmonic detection provides substantial improvements in instrument sensitivity, but demands the empirical determination of data processing matrices.

Jet Propulsion Laboratory (JPL) Laser Hygrometer

The NASA Jet Propulsion Laboratory (JPL) laser hygrometer (JLH) instrument uses a near-IR tunable diode laser coupled into an open-path multi-pass Herriott cell, which is mounted external to the aircraft platform and positioned outside the aircraft boundary layer (May, 1998). The instrument utilizes harmonic detection for high precision measurements of atmospheric water vapor in the UTLS. Three versions have been developed at the Jet Propulsion Laboratory, California Institute of Technology, for use on NASA's ER-2, WB-57, DC-8, and Global Hawk aircraft, and JLH has participated in multiple airborne missions from 1997 to the present. The stated precision of JLH is $\sim\pm 0.10$ ppmv for a nominal 1-s integration period, and an accuracy of $\pm 10\%$ (May, 1998; Fahey et al., 2014).

JLH utilizes a near-IR distributed feedback (DFB) tunable diode laser at ~ 1.4 μm . JLH is capable of operating in two modes: harmonic wavelength modulation spectroscopy (May, 1998; May and Webster, 1993), and direct absorption spectroscopy. As discussed in the introductory section, the advantages of harmonic spectroscopy are fast response and high precision, while the advantages of direct absorption measurements are high accuracy, and a verification of overall instrumental performance. The laser is scanned at a 10 Hz repetition rate through a 2 cm^{-1} spectral region that includes the chosen water vapor absorption line. Second-harmonic detection ($2f$) is utilized for signal enhancement by adding a small-amplitude sinusoidal waveform at a frequency of 10 kHz to the laser current. The detector signal is demodulated at 20 kHz to produce a second-harmonic spectrum. Periodic direct absorption measurements serve as an *in situ* validation of the measurements acquired with the calibrated $2f$ detection technique.

The Herriott cell is made up of two opposing gold-coated mirrors that are mounted in the free stream and strategically placed below the aircraft wing or forward fuselage. The mirror separation is maintained to within a tight tolerance over the wide range of ambient temperatures, e.g., from ~ 180 K to 300 K, by invar rods. The laser and detector are enclosed in an evacuated aluminum housing, which is also mounted external to the aircraft, and is temperature stabilized at 15 °C. The laser beam is directed through a hole in the mirror closest to the laser housing. The beam completes ~ 50 passes in the Herriott cell, in total traversing ~ 10 m, before returning through the same hole and reaching the detector. There is an additional short path in ambient air between the entrance/exit mirror and the window to the evacuated laser/detector housing. Spurious absorption due to water vapor in the very short path inside the housing itself is minimized by maintaining very low pressure ($< 10^{-6}$ hPa) in the vessel.

Laboratory calibrations are used to derive the empirical relationship between the $2f$ spectra and water vapor mixing

ratio. JLH is calibrated in the laboratory utilizing a Thunder Scientific 3900 Low-Humidity Generator as both a water vapor source and as a reference. Additional standards, which can monitor the water vapor mixing ratio at the input and/or output of the chamber, include a National Institute of Standards and Technologies (NIST)-traceable chilled mirror hygrometer from General Eastern, and a mid-IR direct absorption measurement at 5316 cm^{-1} (Troy, 2007). The instrument is placed in stainless steel chamber and calibrated over a wide range in both temperature and pressure to map out the instrument response under conditions representative of those in the UTLS.

NASA Langley/Ames Diode Laser Hygrometer

The NASA Langley/Ames diode laser hygrometer (DLH) utilizes a commercially available mid-IR fiber-coupled tunable diode laser coupled to a long external path to measure water vapor throughout the troposphere and lower stratosphere (Diskin et al., 2002; Livingston et al., 2008). Versions of DLH have successfully flown in many recent field campaigns and on several different aircraft that cover a range of altitudes from near the boundary layer to the lower stratosphere, e.g., the P-3, DC-8, WB-57, ER-2, and the Global Hawk. The long path-length combined with harmonic detection provides excellent sensitivity and rapid time response. The precision of DLH is $\sim 1\%$ (1σ) or 50 ppbv at 20 Hz, with an accuracy of $\pm 10\%$ (Podolske et al., 2003).

In order to cover the orders of magnitude change in ambient mixing ratio from the mid-troposphere to the lower stratosphere, DLH targets different absorption lines in the 1.4 μm spectral region. Weaker lines are used at low altitudes (high mixing ratios) and a strong line is used at high altitudes (low mixing ratios). The laser line is locked to the center of the desired absorption feature with a low pressure reference cell. DLH utilizes $2f$ and/or $4f$ harmonic detection. The laser beam is wavelength modulated at ~ 2 kHz, and detection is accomplished by demodulating the return signal at twice or four times the modulation frequency. The return laser power is also measured for normalization.

All versions of the instrument utilize an open-path, two-pass configuration. The path is defined on one end by a laser transceiver and on the other by a panel of high grade retro-reflecting material. The mounting locations of the laser/detector and retro-reflectors depend upon the aircraft. On the Global Hawk, for example, the pressurized laser transceiver housing is mounted in a payload bay within the aircraft fuselage, and the retro-reflecting material is adhered to a fin mounted below the left wing. This configuration leads to an external round-trip path of 12.22 m, with most of the sample volume outside the aircraft boundary layer, and no inlet effects. The internal path inside the pressurized optical housing is of 0.55 m. Maintaining pressure in this volume and it purging with dry air reduces the sensitivity of the measurement to internal moisture.

DLH is calibrated in the laboratory over a representative range of pressures and water vapor concentrations. The calibration data are incorporated into a multiparameter model, which is used to determine the coefficients that convert the demodulated signal, along with independent measurements of ambient temperature and pressure, to water vapor mixing ratio.

Aircraft Laser Infrared Absorption Spectrometer

Aircraft laser infrared absorption spectrometer (ALIAS) is a high-resolution scanning tunable laser absorption spectrometer designed to fly in a spearpod on NASA's ER-2 or WB-57 aircraft (Webster et al., 1994). The instrument has had many configurations utilizing different IR lasers to target a wide array of atmospheric molecules, e.g., HCl and N₂O. From 2002 to the present it has targeted measurements of total water (water vapor + water in the condensed phase), as well as the isotopologues of water, e.g., HDO, H₂¹⁷O and H₂¹⁸O in the gaseous and condensed phases, throughout the UTLS (Webster and Heymsfield, 2003). The accuracy of the ALIAS H₂¹⁶O measurements is ±10% (Rollins et al., 2014).

ALIAS uses a forward-facing isokinetic inlet, which extends from the front of the spear pod and well outside its region of influence on the flow. The isokinetic design ensures that the sampled particle number density is equivalent to that in the ambient environment. 500 W of heat is applied to the inlet to vaporize any water in the condensed phases prior to detection. In 2011, a mesh with 100 μm openings was inserted into the flow to facilitate the evaporation of larger ice particles in the sample (Rollins et al., 2014). The air is then directed into an internal Herriott cell, which is maintained at ~12 °C by upstream heating. The details of the Herriott cell effective path length and volume vary by the generation of the instrument. An increase in the wavelength of the targeted spectral region from 1.88 to 2.65 μm in 2011, allowed for a significant reduction in the cell volume to its present value of 300 cm³, with a path length of 36 m.

The laser is scanned over the spectral region at 10 Hz, and both direct absorption and second harmonic spectra are recorded (Webster and Heymsfield, 2003). For data reduction of the direct absorption data a Voigt line shape is used in conjunction with spectroscopic parameters measured at JPL, which were within 5% of the HITRAN 2008 values (Rothman et al., 2009). The 2f spectra are mapped to the direct absorption spectra in extensive tests executed prior to flight (Webster and Heymsfield, 2003).

The ALIAS measurements are verified in the field after individual flights, as well as in the laboratory before and after each mission. In the field, the addition of synthetic air containing a known mixing ratio is used as a reference standard for evaluating instrument performance. In the laboratory, more extensive calibrations involve sampling synthetic air containing variable concentrations of water vapor with flows that are continuous over several days. A Thunder Scientific 3900 humidity generator is used to generate these flows, with the values cross checked by a Vaisala humidity sensor (Rollins et al., 2014). To obtain accurate measurements of the isotopic ratios of H₂¹⁶O to its heavy isotopologues, calibrations are executed with a certified water sample with known isotopic composition (Webster and Heymsfield, 2003).

Harvard Herriott Hygrometer

The Harvard Herriott Hygrometer (HHH) measures water vapor via direct absorption in the near-IR utilizing a fiber-coupled tunable diode laser and a multipass Herriott cell (Sargent et al., 2013). In its present configuration, the cell is

integrated into the primary inlet duct of the Harvard Lyman-α hygrometer. Fast flow through the instrument duct, ~70 m s⁻¹, ensures a fast flush time and a rapid time response. The combined instrument, which provides two independent measurements of water vapor in a common duct, has flown missions on NASA's ER-2 and WB-57 aircraft from 2011 to the present. Advances in signal processing and data acquisition systems have made it possible to achieve both high precision and accuracy with a direct absorption technique. HHH has a stated precision of ~<0.10 ppmv for a 1-s integration period, an accuracy of ±5–8%, and a bias uncertainty of ±0.2 ppmv for pressures <500 hPa or mixing ratios ~<600 ppmv (Sargent et al., 2013).

HHH uses a fiber coupled ~1.4 μm DFB laser to scan over a strong water vapor absorption feature, in this case a single rotational-vibrational transition at 7181.16 cm⁻¹. The laser beam is split using a fiber beam splitter to two primary detectors. The main beam, which consists of ~90% of the light, is directed through a hole in one of the two gold-coated mirrors that form the Herriott cell. The mirrors, which are embedded opposite each other ~10 cm apart in the walls of the primary duct of the dual-axis HWV instrument, support a 92 pass pattern for a total absorption path of ~10 m. The beam exits the cell through the entrance/exit hole and is detected by an InGaAs photodetector. In addition to the main cell, 5% of the light is directed through a silicon etalon in order to accurately determine the frequency tuning rate of the laser as it is scanned across the absorption feature.

The use of direct absorption distinguishes HHH from most other airborne laser absorption instruments, which rely on second-harmonic detection to achieve the desired precision. With direct absorption, the accuracy of HHH is theoretically tied only to the accuracy of the state variables, i.e., temperature and pressure, the pathlength, and the spectroscopic parameters from the HITRAN database. However, in practice, any field instrument must be validated in the laboratory to constrain potential sources of systematic error, i.e., water in the path between the laser and detector, which are housed in a thermally regulated pressurized. Pressurization and routine purging with dry air prior to flight reduces the sensitivity of the measurement to internal moisture. Furthermore, the HHH instrument is routinely validated in the laboratory by comparison with multiple standards under conditions that replicate the flight environment as closely as possible. The calibration system and choice of standards are identical to those used for the Harvard Lyman-α instrument.

Harvard Integrated Cavity Output Spectroscopy Isotope Instrument

The Harvard integrated cavity output spectroscopy (ICOS) water isotope instrument is a mid-IR spectrometer which utilizes the off-axis ICOS technique to make *in situ* measurements of water vapor and its major isotopologues, HDO and H₂¹⁸O, in the UTLS in an internal cell (Sayres et al., 2009). The long pathlength provided by this technique provides the sensitivity and accuracy necessary to measure trace atmospheric species at concentrations in the ppbv range. The Harvard ICOS isotope instrument flies on NASA's WB-57 high-altitude research aircraft, and has participated successfully in four field

campaigns from the winter of 2004–2005 to the present. The data acquisition rate of the instrument (1/4 Hz) is a convolution of the data rate needed to achieve the desired precision and the flush time of the detection volume. The stated precision and accuracy of Harvard ICOS varies by molecule. For water vapor the precision is 0.14 ppmv in 4 s, the accuracy is $\pm 5\%$, and the bias uncertainty is ± 0.25 ppmv; for H_2^{18}O the precision is 0.16 ppbv in 4 s, the accuracy is $\pm 5\%$ and the bias uncertainty is ± 0.30 ppbv; and for HDO the precision is 0.10 ppbv in 4 s, the accuracy is $\pm 5\%$, and the bias uncertainty is ± 0.06 ppbv (Sayres et al., 2009).

ICOS is a relatively new cavity absorption technique that forces light from a high-power continuous-wave laser through the rear of the first mirror into a high-finesse optical cavity consisting of a pair of highly reflective mirrors ($R \approx .09998$) (Baer et al., 2002; Paul et al., 2001). The light is trapped in the cavity for tens of microseconds. Light bleeding out of the rear of the second mirror of the cavity is captured and focused on a detector. It is the steady state power emitted from the cavity that is recorded as the laser is scanned across the spectral region of interest. In the Harvard instrument a mid-IR quantum cascade laser operating at 1484 cm^{-1} is used to scan over a region that includes individual rotational lines of H_2O , HDO, and H_2^{18}O . Changes in the steady state power are tied to intracavity losses due to molecular absorption, and the resulting spectrum yields nearly simultaneous measurements of the number density of the absorbing gases within the cell, much as in traditional IR absorption spectroscopy. Because light is trapped within the optical cell for tens of microseconds, however, the effective optical pathlength is several kilometers rather than the tens of meters of a typical Herriott cell, and the instrument sensitivity is correspondingly greater. The Harvard ICOS isotope instrument has an effective optical path-length of nearly 4 km.

The ICOS flow system is designed to (1) minimize the residence time of air in the absorption cell (<1 s), (2) minimize contamination of the air from dead volumes and surfaces, and (3) maintain a constant pressure and temperature within the cell. The flow is maintained by an oil-less scroll pump located at the outlet end of the flow system. Ambient air is brought into the system through a rear facing inlet for particle rejection. The inlet is located well outside the aircraft boundary layer and is heated to prevent condensation. Additional heating downstream ensures that the temperature of the sample is near 25°C , which is equivalent to the temperature of the optical cell. Maintaining a well-defined and constant temperature is important for reducing uncertainties in the measurement. A pinch valve, which allows for high conductance without stagnant volumes, is used to regulate the cell pressure at 53 hPa. A proportional-integral feedback loop between the cell pressure and the valve position maintains a constant cell pressure even as the ambient pressure changes.

The system is capable of bringing both ambient air into the optical cell as well as air from an in-flight gas addition system used for *in situ* calibration. The ICOS instrument is equipped with a gas deck that consists of two high pressure gas bottles capable of delivering dry air or air with a small amount of water and methane to the cell. The first bottle is filled with ultra-pure dry air with less than 0.2 ppmv of water, and the second bottle is typically filled with air containing about 20 ppmv of water

vapor and about 5 ppmv of methane. Periodically during flight the instrument samples air from the calibration gas deck to verify instrument performance *in situ*.

Though water vapor mixing ratios can be calculated directly from spectroscopic parameters obtained from the HITRAN database and physical constants of the ICOS system, laboratory calibrations are routinely performed to verify instrument accuracy and to minimize the impact of any systematic errors. ICOS utilizes the same two water addition systems as Hoxtope for performance verification: a bubbler system and a micro-droplet injector system. The use of dual standards provides a rigorous evaluation of uncertainty.

Chemical Ionization Mass Spectrometer

Principle of Operation

Chemical ionization mass spectrometry is a selective and highly sensitive method for molecular detection and has been used successfully for the *in situ* detection of atmospheric trace species, e.g., nitric acid (HNO_3) and hydrochloric acid (HCl) (Neuman et al., 2000), on NASA's high-altitude research aircraft. Chemical ionization mass spectrometer (CIMS) consists of three primary components: an ion source generator, a mass analyzer, and a detector. Typically, chemical ionization relies on the collision of the molecule of interest, i.e., the analyte, with ions of a reagent gas. The reagent ions are often generated by flowing the gas past radioactive elements in the ion source region. The collision of the reagent ions and the analyte yields the desired ion for detection downstream. An extraction system removes the ions from the sample and directs them through a mass analyzer and ultimately to a detector. Different ion fragments produced during the ionization process will have different mass-to-charge ratios (m/z). These differences allow the mass analyzer to separate the ions. Mass spectra, i.e., measurements of the detector intensity as a function of m/z , are recorded over a selected range. The intensity is directly related to the abundance of each ion present, and thus, through careful calibration, to the initial concentration of the molecular species under investigation.

National Oceanic and Atmospheric Administration CIMS- H_2O

The development of the NOAA CIMS is notable for introducing a new technique to the suite of water vapor measurement methods as well as, for integrating a full calibration system into the flight package. The CIMS- H_2O instrument flew aboard NASA's WB-57 during the MACPEX mission in 2011, and participated in the water vapor intercomparisons during that mission (Rollins et al., 2014). It demonstrated excellent precision, $<\pm 2\%$ ($\pm 2\sigma$, 1 s), and high accuracy $\sim \pm 10\%$ for mixing ratios <150 ppmv (Thornberry et al., 2013).

The CIMS- H_2O was adapted from the existing NOAA CIMS instrument, described by Neuman et al., (2000), to target measurements of H_2O at low mixing ratios in the UTLS aboard the WB-57. Modifications included minor changes to the quadrupole mass spectrometer to convert it from measuring negative ions to positive ions, and the development of a new and compact custom ion source. In contrast to the standard

ionization technique described above, no separate reagent ion flow is needed. Instead a low-pressure flow of sample air is directed through the ion source chamber and exposed directly to α particles emitted from a radioactive source (in this case ^{241}Am foil). The resulting cascade of ion–molecule reactions produces protonated water ions (H_3O^+) as a stable end product, with the number of H_3O^+ ions monotonically, but nonlinearly related to the water vapor mixing ratio in the sample. The relationship is determined empirically through frequent calibration in both flight and the laboratory over the range of atmospherically relevant mixing ratios. The production of H_3O^+ ions depends on the pressure and flow through the ion source. As a result, both are tightly controlled in order to maintain consistent measurement sensitivity.

The instrument samples ambient air through an inlet line that is oriented perpendicular to the aircraft flight direction in order to reject condensed phase water. The inlet port extends below the aircraft fuselage and well outside the boundary layer of the aircraft. The tip of the inlet is heated to prevent condensation, and more heat is applied along the length of the inlet line. The pressures inside the inlet system and ion source region, and the resulting flow through the ion source, are held constant within their respective tolerances over a wide range of ambient pressures and temperatures. Sample residence times are <0.1 s at ambient pressures below 500 hPa allowing for data acquisition at a rate of 10 Hz. The data are then averaged to 1 s.

The CIMS- H_2O instrument was intentionally designed to maintain highly regulated internal temperatures, pressures, and flows, and to be insensitive to changes in the ambient environment. Because of these careful design considerations, CIMS- H_2O operates, and is calibrated, identically in flight and in the laboratory. Calibrations are run every 45 min in flight. The CIMS- H_2O uses two independent calibration sources to sample known mixing ratios of water vapor. The standards are (1) a mixture of water vapor in air near 5 ppmv stored in an onboard stainless steel cylinder, and (2) dynamically controlled flows of air with water vapor mixing ratios between 0.5 and 150 ppmv, generated by the Pt-catalyzed oxidation of onboard H_2 standards (Rollins et al., 2011). In both cases the calibration flow is capable of completely displacing the ambient flow. The uncertainty associated with each system is less than $\pm 10\%$, and the two systems have demonstrated consistency with each other both on the aircraft and in the laboratory. The entire calibration system is routinely checked against an NIST-traceable MBW-373LX reference hygrometer on the ground.

Capacitance Hygrometer

Principle of Operation

Capacitive humidity sensors relate measurements of the capacitance between two charged plates to the ambient water vapor mixing ratio, through the measurement of relative humidity (RH). RH is defined as the vapor pressure of water in the air sample ($p_{\text{H}_2\text{O}_{\text{samp}}}$) divided by the saturation vapor pressure with respect to liquid water or ice air at the temperature of the sample ($p_{\text{H}_2\text{O}_{\text{sat}}}$), i.e., $\text{RH} = p_{\text{H}_2\text{O}_{\text{samp}}} / p_{\text{H}_2\text{O}_{\text{sat}}}$. The plates are separated by a polymer membrane that adsorbs and desorbs water in order to reach equilibrium with the vapor pressure of water in the surrounding air. The

capacitance is, therefore, roughly proportional to the RH, with the exact relationship determined by sensor-specific calibration. Given the measurement of RH, the saturation vapor pressure, which can be calculated using one of several versions of the Clausius–Clapeyron equation (Murphy and Koop, 2005), and a measurement of the sample pressure, the mixing ratio of water vapor can be determined. These devices can provide a very compact means of detecting water vapor *in situ* on board balloons and aircraft.

The response time of these devices is tied to the polymer's ability to absorb and desorb water and on the temperature of the sensor itself. Chemical contamination of the polymer by molecular species other than water vapor can reduce its ability to absorb water and lead to a dry bias in the measurement. Furthermore, at the cold temperatures of the UTLS, e.g., less than -60°C , the response time slows to ~ 1 min, limiting the utility of these sensors in this region.

Each individual device requires careful and regular cleaning and calibration to ensure optimal performance and measurement accuracy.

The Measurement of Ozone and Water Vapor by Airbus In-Service Aircraft Humidity Device

The measurement of ozone and water vapor by airbus in-service aircraft (MOZAIC) project deploys these capacitive devices, which operate autonomously, on commercial aircraft to obtain an extensive data set of RH and water vapor measurements throughout the lower to middle troposphere (Marengo et al., 1998). Regular measurements of ozone, carbon monoxide and nitrogen oxides are also obtained. MOZAIC was initiated in 1993, and represents a highly successful collaboration among the European scientific community, aircraft manufacturers, and the airlines. Plans to extend the MOZAIC research project into the future are in place under the European research consortium Integration of routine Aircraft measurements into a Global Observing System (IAGOS) (Petzold et al., 2012).

For water vapor, the MOZAIC humidity device (MHD) is a special airborne capacitive humidity sensor developed by Aerodata (Braunschweig, Germany). The design utilizes a humidity and temperature transmitter manufactured by Vaisala (Helsinki, Finland). The capacitive sensor (Humicap-H, Vaisala) is paired with a resistive temperature device in a special inlet and associated housing, which is mounted to the aircraft. The inlet, produced by Rosemount (United States) is positioned out of the boundary layer of the aircraft skin, and is designed to simultaneously protect the sensors from particles and minimize contamination of the sample by the inlet walls. The Rosemount housing is installed on a removable plate, located on the left side of the fuselage in the nose of the aircraft.

Experience has shown that with regular calibration, i.e., every 500 h of flight operation, the accuracy of the RH measurement is typically better than $\sim \pm 10\%$, with a response time of approximately 4–10 s, for data acquired up to 12 km. Each unit is calibrated against a water vapor reference instrument over the relevant air temperatures and pressures in the environmental simulation chamber at the Forschungszentrum Jülich, Germany (Helten et al., 1998, 1999). As mentioned above, the performance of these devices in the stratosphere is

not suitable for quantitative water vapor measurements (Bange et al., 2013; and references therein). (Airborne Measurements for Environmental Research: Methods and Instruments, edited by Manfred Wendisch and Jean-Louis Brenguier, is another excellent resource.)

Conclusions

The need for accurate measurements of UTLS water vapor has been repeatedly delineated in the peer-reviewed literature, and much progress has been made to meet the stringent requirements set by the scientific objectives. Results from two recent intercomparison campaigns, one executed in the laboratory (AquaVIT) and one *in situ* (MACPEX), demonstrate improved agreement among several aircraft and balloon-borne hygrometers with long histories of measuring in the UTLS (Fahey et al., 2014; Rollins et al., 2014). These sensors represent four of five techniques discussed here, e.g., frost point, photo-fragment fluorescence, IR absorption, and chemical ionization mass spectrometry. The joint intercomparison results establish that each technique has intrinsic skill for measuring atmospheric water vapor, and that the reference standards and calibration procedures for the individual sensors are consistent with each other to within their stated uncertainties. Both intercomparisons yielded comparable results, with good agreement at the level of $\pm 10\%$ ($\pm 1\sigma$) for mixing ratios >10 ppmv, and agreement degrading to $\pm 20\%$ ($\pm 1\sigma$) for the region between 1 and 10 ppmv. Furthermore, the similarity in the results of the two intercomparison campaigns indicates that the gap between agreement found in the laboratory and agreement demonstrated in flight is closing.

Despite these notable improvements, the intercomparison results also show that routine agreement at the level needed to satisfy the scientific objectives still has not been achieved. Indeed, the history of intercomparisons demonstrates that the level of agreement among instruments can vary over time, and regular monitoring is recommended to address issues of long-term accuracy, especially with respect to trend detection. At present, no research instrument has demonstrated beyond a reasonable doubt either an accuracy or long-term precision of $\sim 5\%$ or better, especially at the lowest mixing ratios encountered in the UTLS. Correcting this will require continued effort from the community in setting instrumental requirements, in maintaining an objective approach to examining the different data sets, as well as in planning and funding repeated intercomparison campaigns of the quality demonstrated during AquaVIT and MACPEX. Furthermore, rigorous calibration and validation efforts on the part of individual experimenters should continue, along with efforts to improve instrumentation. Rollins et al. (2014) suggest that the larger differences, evident at the lower mixing ratios in both intercomparisons, are most likely due to variable background artifacts. Thus, future efforts at improving instrument performance should be aimed at addressing potential sources of measurement bias, whether due to sampling or signal errors. Finally, transparency and documentation of these efforts will enable the community to review the results and maximize their utility in assessing long-term precision and measurement accuracy.

Nomenclature

$L_{v,O}$ Radiance detected by observer located at x_O ($W/(m^{-2} \text{ sr cm}^{-1})$).

$L_{v,S}$ Radiance of background source located at x_S ($W/(m^{-2} \text{ sr cm}^{-1})$).

$B_v(T)$ Radiance emitted by blackbody source of temperature T ($W/(m^{-2} \text{ sr cm}^{-1})$).

k_v Absorption coefficient (m^{-1}).

$\delta_v(x_1, x_2) = \int_{\tilde{x}=x_1}^{x_2} k_v(\tilde{x}) d\tilde{x}$ Optical thickness between locations x_1 and x_2 (-).

$\tilde{x}$ Is the coordinate along the curved path determined by the line-of-sight, directed from the observer to the source ($x_O < x_S$) (m).

Synopsis

This article provides an overview of passive remote sensing techniques in the infrared and far-infrared spectral domain with emphasis on the observation of the atmosphere's chemical composition. At first, the formation of spectral lines is outlined and the radiative transfer equation is presented. This allows for a description of the appearance of atmospheric spectra as a function of chosen observer location and observing geometry. Different types of measurement devices for recording infrared spectra as grating, Fabry-Perot, and Fourier transform spectrometers are introduced. The quantitative analysis of infrared spectra is surveyed: methods applied for the retrieval of trace gas concentrations from spectra are introduced and some inherent limitations of the remote sensing approach are pointed out. The final section provides some examples of past and current sensors, and presents illustrative results achieved with these instruments.

Introduction

Passive remote sensing of the atmosphere by analyzing the ubiquitous infrared (IR) radiation field offers the possibility to measure a wide variety of atmospheric parameters simultaneously. Large sampling volumes can be investigated, and in the case of spaceborne instruments a considerable fraction of the global atmosphere can be observed within a single day.

The impact of the sampling volume on the radiation field depends on its density, its temperature, and on its chemical composition. The volume may also contain aerosols, which change the radiation depending on their optical properties and allowing a constraint of their optical properties allowing to constrain the chemical composition and the volume distribution of the particles.

By offering such a wide set of observables, the passive remote sensing in the IR spectral domain contributes significantly to many key problems of atmospheric research: The deduced global fields of various trace gases help to improve the understanding of physical and chemical processes. In the case of the stratospheric ozone depletion, the simultaneous observation of ozone together with many of the ozone-related species imposes severe constraints to the chemical transport models. The considerable time period since the invention of the method (ground-based atmospheric measurements started in the 1940s) allows to monitor the chemical evolution of the present atmosphere in response to natural and anthropogenic influences. Spectrally resolved measurements of the global IR

flux upwelling from the top of the atmosphere supply important information concerning the Earth's radiation budget and its drivers, such as temperature structure, distribution of water vapor, and various types of clouds.

This outline is organized in the following way: First, we sketch the origin of the spectroscopic features observable in the IR spectral region, and describe the radiative transfer in the atmosphere. Next, the geometric aspects of the observation are outlined. In the following section, the various experimental methods for probing the radiation field are introduced, their spectral coverage and resolution differing by orders of magnitude. Since the sensor has to be adapted carefully to the requirements defined by the desired data products and their accuracy, the problem of analyzing the measured radiances is at the very heart of remote sensing experiments. A further section is devoted to the fundamentals of this analysis procedure. In the end, we present some examples of remote sensing experiments together with illustrative results.

Spectroscopic Features

The photon energies in the IR and far-infrared (FIR) spectral regions correspond to energies involved in rovibrational and pure rotational transitions of molecules, respectively. Observations with sufficient spectral resolution reveal the complexity of atmospheric IR spectra, the molecular signatures comparable to unique fingerprints of the corresponding constituents. Not all

molecules interact with the IR radiation field, only those with a permanent electric dipole moment can efficiently 'serve as an antenna' when rotating, and only those with a variable electric dipole moment correlated with the displacements of the atomic constituents do so when vibrating. In case of the prevalent molecular constituents, the interaction of a magnetic dipole or an electric quadrupole with the radiation field can also be detected.

In the framework of quantum mechanics, the spectral positions of the spectral lines are determined by the energy differences between discrete eigenstates of the molecule, which are designated by a set of quantum numbers. The resulting line strength is determined by the transition probability between the states involved, and by the fraction of molecules populating the initial level. In the spectra of simple molecules with a high degree of symmetry and constituted by only a few atoms, the rotational lines can be resolved, whereas complex molecules show broadband features, with the underlying structure not resolvable, since the spacing of the lines is narrower than the width of individual lines. In any case, the spectral signatures are highly characteristic, and the concentration of each species in a mixture of gases can be deduced from spectra of sufficient spectral resolution unambiguously. Since the moments of inertia as well as the effective masses involved depend on the atomic masses, the spectral features of isotopomers are characteristic and thus they can be discerned by IR and FIR remote sensing. Figure 1 shows a measured atmospheric spectrum in the 700–970 cm^{-1} range.

The spectral characteristics of aerosols, cloud droplets, and ice particles do not show isolated lines. Instead, broadband spectral features are observed due to the overwhelming large number of interacting molecules involved. The resulting emission, absorption, and scattering characteristics depend on size, composition, shape, and orientation of the particle. This does not mean, however, that all these properties are recoverable by remote sensing of an ensemble of particles in the

atmosphere. If strongly simplifying assumptions are made (parameterized size distribution, homogeneity, and sphericity in case of solid particles), then the chemical composition, the mean size, and the total volume of the observed particles can be deduced to some extent.

Atmospheric Radiative Transfer

To relate the observed IR radiances with the state of the atmosphere, the modeling of the radiative transfer is of crucial importance. First, the raypath through the atmosphere has to be determined, as it is bent according to the local density (and water vapor) gradient. The spectrum observed at a chosen location and along a chosen line-of-sight depends on the radiance of a background source (e.g., sun, ground), if present, and on the emission, absorption, and scattering in each atmospheric element along the raypath to the observer. If scattering of radiation into the line-of-sight can be neglected as valid in the IR in the absence of clouds and aerosols, these contributions depend on local properties of each atmospheric path element solely.

Besides temperature, the pressure has a strong impact on the radiative transfer through an atmospheric element of given partial column. Frequent collisions disturb the molecule during the transition, which leads to a pressure broadening of each spectral line. In higher altitudes, the line width is dominated by the Doppler broadening associated with the thermal motions of the molecules. Since the Doppler width is proportional to the frequency of the line, the boundary between the pressure-broadening and Doppler-broadening height regime increases from about 20 km in the near-IR to about 60 km in the FIR region.

According to the assumption of local thermodynamic equilibrium (LTE), the emission and absorption characteristics of each atmospheric element are fully specified by chemical composition, partial pressures, and a single thermodynamic

Figure 1 Measured limb spectrum from 770 to 970 cm^{-1} at 12.8 km tangent height using the airborne Fourier transform spectrometer MIPAS-STR. Signatures of various species are marked.

variable, the temperature. If the population of an energy level involved in a transition deviates from the Boltzmann distribution determined by the temperature of the atmospheric element (e.g., due to chemical reactions or due to interaction with energetic solar photons), so-called non-LTE conditions apply for this transition. This is most likely to occur in high altitudes, where the mean free path is large.

If the impact of aerosols cannot be neglected, the calculation of the resulting spectrum may be complicated tremendously. If scattering by the particles into the line-of-sight is neglected, these are treated formally as a further absorbing and emitting component in the air parcel. The total extinction cross section of the particles is used for the calculation of an approximate optical thickness. In a more refined approximation, photons scattered into the line-of-sight are taken into account, but it is assumed that multiple encounters of a given photon with aerosols can be neglected. This requires to calculate radiances from all representative directions at the position of the air parcel. If multiple scattering is taken into account, the resulting radiances and the aerosol distribution become intimately related, and the radiative transfer calculation needs to be performed in an iterative manner or by using Monte Carlo methods.

Without scattering and under LTE conditions, the radiative transfer equation reads

$$L_{v,O} = L_{v,S} \cdot \exp(-\delta_v(x_O, x_S)) + \int_{\tilde{x}=x_O}^{x_S} k_v(\tilde{x}) B_v(T(\tilde{x})) \exp(-\delta_v(x_O, \tilde{x})) d\tilde{x} \quad [1]$$

with

$L_{v,O}$ radiance detected by observer located at x_O ,
 $L_{v,S}$ radiance of background source located at x_S ,
 $B_v(T)$ radiance emitted by blackbody source of temperature T ,
 k_v absorption coefficient,

$\delta_v(x_1, x_2) = \int_{\tilde{x}=x_1}^{x_2} k_v(\tilde{x}) d\tilde{x}$ optical thickness between locations x_1 and x_2 ,

x is the coordinate along the curved path determined by the line-of-sight, directed from the observer to the source ($x_O < x_S$).

Figure 2 shows calculated atmospheric spectra for a spectral interval extending from 783 to 789 cm^{-1} in the mid-IR region.

Figure 2 (a)–(d): Calculated atmospheric spectra in the same spectral interval for various observational modes: At top (a) a ground-based solar absorption spectrum is shown. Some of the most striking features are labeled. All narrow absorption lines belong to O_3 , the strong H_2O line around 784.5 cm^{-1} is completely opaque. The second diagram (b) shows the spectrum emitted by the atmosphere as observed from the ground. The spectral features now appear in emission, the O_3 signatures are strongly damped. The saturated H_2O line around 784.5 cm^{-1} reaches the limiting blackbody radiance of the atmospheric temperature near ground. In the third diagram (c), a nadir spectrum according to the view from a satellite is shown. The warmer ground acts as a background source, so the spectral features appear in absorption. Note the changed ordinate scale and the poor contrast between lines and continuum in (b) and (c) as compared to (a). This is, because the temperatures involved are not so different as in case (a), where the hot sun outshines the atmospheric emission. In (d), a limb spectrum for a tangent height of 20 km is shown. The emission of the stratospheric O_3 dominates, whereas the strong H_2O feature seen in (a)–(c) is not detectable, due to the low amount of H_2O in the stratosphere.

According to the radiative transfer equation, the character of the resulting spectra depends on the location of the observer, the line-of-sight, and the temperature of a background source, if present.

Modes of Observation

The observer can choose spectral resolution, location, and line-of-sight of the instrument according to his aims and the justifiable expenditure. Figure 3 shows some possible modes of observation.

A ground-based instrument can be used to observe the atmosphere in emission or absorption (in the latter case the Sun or the Moon serves as a background source). In the FIR region, ground-based observations are impossible, since the atmosphere is by far too opaque due to the strong absorption of water vapor. In the IR, ground-based observations in emission suffer from the fact that, due to the number density and temperature stratification of the atmosphere, the observed signal stems mainly from the lowermost layers of the atmosphere. Therefore, only a few kilometers above the instrument can be investigated by this method. Ground-based observations in absorption with high spectral resolution are in wide use for monitoring of trace gases in the free troposphere and stratosphere, but are also applied to local environmental studies, e.g., plume observations.

An airborne instrument can be operated on an aircraft or balloon. The observations may be performed in absorption or emission. Whereas balloon-borne experiments reach heights of 40 km, even high-altitude aircraft are limited to ceilings of about 20 km. A balloon offers in principle the possibility of long duration flights. On the other hand, an airplane can probe extended atmospheric regions along a preselected flight track. The location of the sensor on an airborne platform permits upward-directed, downward-directed, or tangential line-of-sights. Limb measurements, either by sounding different tangent heights in emission or by observing the rising or

lowering Sun near the horizon, allow to construct vertical profiles with considerable vertical resolution below the flight level, whereas nadir sounding offers high lateral resolution, but poor vertical resolution, since this information has to be deduced from the combination of various spectral intervals with different optical thicknesses, with their contributions to the observed radiances peaking at different height levels. Upward-directed observations from a given flight level have to rely mainly on the pressure broadening and temperature dependence of spectral lines to deduce the vertical distribution of the investigated species as in the case of ground-based measurements, an exception being upward sensing during ascent or descent.

A satellite-borne instrument offers global coverage and continuous operation over several years. The observations are performed in limb emission, nadir, or solar occultation mode during sunset and sunrise. The orbits range from heights of several hundred kilometers with orbital periods of about 1.5 h to geostationary orbits. The oblateness of the Earth can be used to introduce a precession of the inclined orbital plane of the satellite, so that e.g., a sun synchronous orbit can be achieved. In the case of solar occultation, the number of observations, their distribution in local time, and latitude are quite restricted. Limb sounding and occultation observations offer the best sensitivity due to the large effective path lengths probed, but are essentially restricted to tangent heights where the spectral signatures under investigation are not saturated and to line-of-sights that are free from clouds. Nadir sounding is preferable for the investigation of the troposphere, since the impact of clouds is minimized.

Instrumental Techniques

Various experimental devices are in use to measure atmospheric radiances.

If a quite low spectral resolution is sufficient, spectral windows can be defined simply by using an arrangement of optical bandpass filters and/or dichroics (e.g., LIMS Limb

Figure 3 Some examples of remote sensing geometries. For details see text.

Figure 4 The Fourier spectrometer MIPAS-B. The beamsplitter is located in the quadratic turret near the center of the image. To the right, the pendulum structure generating the path delays can be seen. Some technical details of the experiment are given in the subsection ‘balloon-borne instruments’ in the last section ‘some experiments and results.’

Infrared Monitor of the Stratosphere, launched in 1978). Modern IR filters combine the transmission properties of substrate materials with the Fabry–Perot-like transmission characteristics of a multilayer coating to adjust the desired bandpass. Filters may show some leakage outside the intended spectral interval and may underlie aging effects, their optical properties being not fully stable.

If higher spectral resolving power is needed, grating spectrometers may be favorable. The simplest form is the monochromator, with a single detector element scanning the spectrum sequentially. The grating spectrometer gained considerable attraction due to the increasing availability of detector arrays in the near- and mid-IR spectral region.
